* Title: The application of fossil grass-phytolith analysis in the reconstruction of late Cainozoic environments in the South African interior.

ABSTRACT

Grass-dominated ecosystems occupy a primary position with regard to current debates concerning key events in faunal turnover and human evolution in Africa. Our knowledge of how grass-dominated ecosystems in southern Africa have reacted to periods of global warming and cooling in the past is provided by a broad range of proxy data sources, most notably pollen and stable isotope records. Phytolith analyses provide an alternative fossil record of environmental change and are now progressively becoming a conventional analytical approach in palaeoenvironmental research. The grass family (Poaceae) produces abundant silica bodies, especially within specific and specialized silica cells located in costal zones of the leaf epidermis. In addition to being highly resistant to decomposition, grass phytoliths show markedly varied and distinct morphologies. In this study a central hypothesis, namely that the morphology of grass short-cell phytoliths consistently follows meaningful environmental traits that are rooted in the relationship between phytolith shape and the ecological niche of grasses, was investigated by interpreting morphologically diagnostic grass phytolith assemblages according to their association with the ecological requirements of the grass species that produces them, irrespective of taxonomic affiliation. An effort was therefore made to assign ecological meaning to short-cell phytoliths by comparing a range of ecological preferences in modern grasses with the phytoliths that they produce, rather than just using phytoliths to discriminate between grass subfamilies, tribes or genera. This entailed a

systematic investigation of grass leaf epidermis from a collection of 309 species, followed by an assessment of the ecological significance of grass-short-cell phytoliths within a quantitative model. The model allowed for comparison of geographically diverse grass phytolith assemblages by converting them into one homogenous group represented by ecological categories. Several meaningful ecological trends were demonstrated by results in this study, and it is suggested that short cell phytolith association in grasses is primarily driven by a temperature gradient, marked by cool versus warm growing temperatures and reflected by grasses utilizing the C_3 and C_4 photosynthetic pathway. The study gives emphasis to the importance of investigating phytolith systematics with the aid of adequate comparative reference collections.

General Introduction

Introduction

A large amount of research has been generated with regard to southern hemisphere climate changes during the late Cenozoic, which shows that the impact of orbital forcing and the influences of high-latitude ice volumes were major driving mechanisms of southern hemisphere climate evolution (DeMenocal 1995; Partridge *et al.* 1997). In addition, the evolution of grass-dominated ecosystems has received considerable attention over the past two decades, especially concerning the time period that is for the most part relevant to human evolution (Retallack 2001; Cerling *et al.* 1997; Vrba 1995; Jacobs *et al.* 1999). The reason is because grass-dominated ecosystems occupy a primary position with regard to current debates concerning key events in faunal turnover and human evolution in Africa (Vrba 1995; Scott 2002; Bobe and Behrensmeyer 2004).

During the last five million years several major cooling and warming episodes have impacted on the Earth's climate within an overall trend towards global cooling and aridification (DeMenocal 1995; Partridge *et al.* 1997). These cycles, also known as Milankovitch cycles, are astronomical permutations of the earth's orbital eccentricity, tilt and orientation of its spin axis that influenced climate changes at different times with the shortest cycle of 23 000 years prominent prior to 2.8 million years ago, a 41 000 year cycle dominating between 2.8 million and one million years ago and a 100 000 year cycle governing from one million years onwards (DeMenocal 1995; Partridge *et al.* 1997). Biotic reactions to climate changes of this magnitude varied

from extinction to speciation - responses that, according to the habitat hypothesis, are major driving mechanisms of evolutionary change (Vrba 1995).

In this instance the expansion and contraction of grasslands in Africa played an important role in creating prospects for vicariance and speciation (Cerling *et al*. 1997, Vrba 1995). Our knowledge of how grass-dominated ecosystems in southern Africa have reacted to periods of global warming and cooling in the past is provided by a broad range of proxy data sources, including sedimentary, biological and archaeological evidence (Deacon & Lancaster 1988; Vrba *et al*. 1995; Shaw & Thomas 1996; Partridge *et al*. 1997, 2004; Scott 1999a, 1999b, 2002). The most comprehensive records of late Neogene grasslands in the central interior of South Africa are derived from faunal studies, pollen sequences and stable isotope records (Brink 1987, 1988; Brink and Rossouw 2000; Scott 2002; Lee-Thorpe and Talma 2000; Rossouw 2006; Hopley *et al*. 2007). Whereas fossil vertebrate fauna and stable carbon isotopes from fossil enamel, paleosols, speleothems and fossil hyrax dung have added considerably to the proxy data record of palaeo-grassland environments, pollen records have presented the most direct access to plant communities of the past and is one of the most common methods of palaeoenvironmental reconstruction, providing key records of vegetation change and climatic fluctuations since the Cretaceous in southern Africa (Coetzee 1967; Klein 1984; Scholtz 1985; Van Zinderen Bakker 1984, 1989, 1995; Scott *et al*. 1995, 1999b, 2002; Lee Thorp and Talma 2000).

Refinement of regional patterns in grassland history is hampered by lack of identification of grass pollen data below family level and the incapability of carbon

isotope analysis to distinguish between C_3 grass and dicotyledonous vegetation (Mulholland 1989; Scott 2002). The problem is compounded by an overall scarcity of terrestrial pollen records, which also impedes palynological investigations of early grassland expansion on the subcontinent (Chase and Meadows 2007). Lately, phytolith analyses have provided an alternative fossil record of environmental change throughout the Neogene and are now progressively becoming a conventional analytical approach in palaeoenvironmental research (Piperno 1988, 2006).

The term phytolith is a general description for soluble, hydrated silica that is deposited within a variety of plant types (Piperno 1988, 2006). Hydrated silica is also described as opal phytoliths, plant opal, colloidal silica or biogenic opal. These terms generally include both the typical silica bodies formed in specialized silica cells as well as uncharacteristic silica bodies sometimes present in other epidermal cells of living plants. Phytoliths are useful for palaeoenvironmental studies because it is inorganic, resistant to oxidation and can be found in a variety of sedimentary contexts that lack pollen (Jones and Beavers 1963; Rovner 1971, 1983, 1988; Pearsall 1982; Mulholland 1989; Piperno 1988, 2006).

The study of phytoliths is a comparatively young discipline with regards to palaeoenvironmental studies and has also developed as a tool in a wide variety of applications (Bryant 1993). Phytoliths were already known from historical observations of plant material and was observed in living plants by a German botanist, called Struve, in 1835 and Ehrenberg in 1841 and 1846 (Piperno 1988). Silica bodies noted in horsetails and grasses were referred to as ‘silex’ by John Lindley, a professor of botany at the University of London until 1860 (Piperno 1988).

The siliceous tissue of plants in windblown dust is also mentioned by Charles Darwin during his travels on the H.M.S. Beagle over two hundred and fifty years ago (Piperno 1988). Ehrenberg developed the first classification system for phytoliths in 1854 and recognized several dozen types of phytoliths (Piperno 1988).

Already at an early stage, opal phytoliths were used as an "index mineral" by comparing amounts, shapes and sizes of opal extracted from soils with those from plants (Beavers and Stephan 1958). Smithson (1958) and Wynn Parry and Smithson (1958, 1964) showed that phytoliths from British soils could be assigned to particular grass tribes or groups of tribes. Baker (1959) analyzed phytoliths in soils for shape distribution and found that the phytolith forms identified can be an effective indicator of the vegetation history. Jones (1964) noted the palaeoenvironmental potential of phytoliths after identifying silica bodies in Cenozoic sedimentary rocks. Oberholster (1968) explained the occurrence of plant opal in two soil profiles from Springbok Flats, South Africa in terms of pedoturbation. Fossil sediments from Western Victoria in Australia were analyzed to test the stability of opal phytoliths in terms of long term preservation (Gill 1967). Armitage (1975) demonstrated the potential use of phytoliths as indicators of herbivore diets when phytoliths were extracted from dental calculus on the teeth of modern cattle. Rovner (1971, 1988) attempted to show the level at which opal phytoliths are taxonomically significant in palaeoecological studies and provided a discussion of phytoliths from various archaeological sites. Phytoliths from soils were used to reconstruct prehistoric and early historic agricultural activities in Hawaii (Pearsall and Trimble 1984). Plant material and soils were analyzed for maize and wild grasses phytoliths in a comparative study in order to recognize

archaeological maize in Panama (Piperno 1984). Fossil pollen and phytoliths were used to document vegetation changes throughout a period of loess accumulation during the Pleistocene in Nebraska, USA (Fredlund *et al.* 1985). Ollendorf (1987) conducted a comparative study of phytoliths obtained from archaeological sediments at the Iron Age site of Tel Miqne in Israel. Palaeodiet preferences in Pleistocene herbivores were explored looking at dental boluses and the silica remains it contain (Akersten *et al.* 1988). A textbook on phytolith analysis provided a comprehensive summary of the discipline and an up to date account of past phytolith research (Piperno 1988). Research on tropical angiosperms from Panama provided an account of the occurrence and morphology of phytoliths in their reproductive structures (Piperno 1989). Using stereological identification methods, Russ and Rovner (1989) distinguished wild *Zea* varieties from cultivated primitive maize for archaeological comparison. In a quantitative study, the taphonomy and morphology of phytoliths from coastal dune sediments were investigated to determine ancient human occupation in the UK (Powers *et al.* 1989). Ciochon *et al*. (1990) identified phytoliths from the enamel surfaces of the teeth of the extinct Asian ape from Liucheng Cave in China. Retallack *et al.* (1990) and Retallack (1992) described wooded grassland conditions at Fort Ternan, Kenya, 14 million years ago by the identification of grass short cell phytoliths. Dugas and Retallack (1993) undertook a SEM investigation of fossilized grass plant material in Middle Miocene paleosols from Fort Ternan, Kenya, showing details of grass short cell phytoliths with comparison to the most similar living grass genera. Fredlund and Tieszen (1994) used modern phytolith assemblages from the North American Great Plains as proxies for past

environmental changes and followed it up with a statistical analysis of modern phytolith assemblages to interpret fossil phytolith assemblages in terms of Late Pleistocene climate changes (Fredlund and Tieszen 1997). Piperno and Pearsall (1993) showed differences and similarities in the reproductive structures of maize and teosinte from North and South America. Fox *et al.* (1994) identified grass-like phytoliths on the surface of historical human teeth from Spain, using SEM and Middleton and Rovner (1994) described a method for the extraction of phytoliths from herbivore dental calculus. Rovner (1994) used phytolith analyses to reconstruct 200 years of floral history of the Harpers Ferry historical site in West Virginia, USA. In an attempt to identify rice phytoliths from early agricultural sites in Thailand, Kaelhofer and Piperno (1994) conducted a comparative study of mainly grasses from the region. Alexandre *et al.* (1997) conducted quantitative analyses of grass and dicotyledonous phytoliths using indices to provide a palaeoenvironmental history of Holocene lake sediments in Senegal and the Congo. Phytoliths in contemporary, Holocene and Pleistocene sediments from Ethiopia were applied to facilitate the temporal differentiation of regional vegetation over time (Barboni *et al.* 1999). Runge (1999) presented a classification scheme of soil phytolith assemblages as a guide to characterize rain forest and grassland vegetation in central Africa. Late Pleistocene and Holocene sediment cores from Tswaing Crater in South Africa provided grass phytoliths that were used as a proxy for palaeoclimatological processes (McLean and Scott 1999). Mercader *et al.* (2000) applied phytoliths of grasses and arboreal plants, extracted from Late Pleistocene and Holocene sediments, as a proxy for palaeovegetation dynamics in the Ituri Forest of the Congo. The application of grass

phytolith assemblages as proxies for palaeoclimatic shifts, was further explored by Mulder and Ellis (2000) using South-West African grass leaf phytoliths. McClaren and Umlauf (2000) investigated the potential for carbon isotopes in phytoliths to estimate long-term desert grassland dynamics in southwestern North America. Gobetz and Bozarth (2001) extracted phytoliths from dental calculus removed from the teeth of Late Pleistocene mastodons. Wallis (2001) studied phytolith assemblages as an alternative source of vegetation history for tropical savannah regions in northwestern Australia. Madella *et al.* (2002) carried out a phytolith analysis of archaeological sediments to interpret subsistence behaviour and mobility patterns of Neanderthals from Amud Cave in Israel. Carnelli *et al.* (2002) suggested a new microanalytical technique for application in palaeoenvironmental research by showing that woody and herbaceous phytoliths can be distinguished based on the amount of aluminum found in the phytoliths they produce. Chemical analysis of occluded carbon in phytoliths suggested important ramifications for the application of $\delta^{13}C$ analysis on C_3 and C_4 plant matter due to the highly depleted state of the occluded organic carbon in charred organic material (Krull *et al.* 2003). Albert *et al*. (2003) conducted a quantitative analysis of grass and dicotyledonous phytoliths from Mid to Late Pleistocene hearths and associated sediments at Hayonim Cave in Israel. In a related study, Elbaum *et al* (2003) presented a method to distinguish between burnt and unburnt phytolith assemblages in archaeological sites by measuring the refractive indices of individual phytoliths. Abrantes (2003) provided a 340 000 year continental climate record from tropical Africa based on a quantitative analysis of C3 and C4 grass phytoliths from Mid to Late Pleistocene sediment cores in the

Equatorial Antlantic. In Urugauy, Iriarte (2003) studied a range of grass taxa and nine modern soil samples by applying multivariate analysis to discriminate between cross-shaped phytolith assemblages in the identification of maize from archaeological sites. Phytoliths extracted from plant remains and archaeological sediments from Panama were analyzed in a comparative study in order to identify maize in neotropical regions (Pearsall *et al.* 2003). Piperno (2003) presented a review of the earliest remains of maize found in Ecuador based on phytoliths recovered from food residues, as well as comments made on the technique which identifies remains of vegetative structures of maize. In an additional investigation, Pearsall *et al*. (2004) identified phytoliths and starch granules recovered from stone tools at Real Alto in Ecuador. Thorn (2004a) provided an annotated bibliography of phytolith studies with photographic atlas of selected New Zealand subantarctic and subalpine phytoliths. Through a quantitative analysis of grass phytoliths from fossil sediments, Thorn (2004b) also suggested that C_4-grasslands, and a minor woody component, were regionally predominant in Queensland, Australia during late Holocene times. Stromberg (2004, 2005) presented a record of grassland evolution in the central Great Plains of the USA, based on the analysis of soil phytolith assemblages from late Tertiary sediments. Harvey and Fuller (2005) based the development of rice and millet processing models for Neolithic sites in North-Central India on phytolith assemblages while Boyd (2005) used phytoliths from aeolian sediments to study regional palaeoenvironmental change during the Holocene in the northern Great Plains of Canada. Bremond *et al.* (2005) demonstrated two phytolith indices to distinguish between grasslands in tropical areas and presented a new phytolith proxy to gain insight into grass water

stress. Prasad *et al.* (2005) reported the presence of phytoliths, including that of grasses, identified in fossilized coprolites of titanosaurid sauropods that lived about 65 to 71 million years ago in central India. Late Holocene human coprolites from southwestern North America show phytoliths as well as calcium oxalate bodies from desert suculents in human diet, and suggest that calcium oxalate phytoliths from desert succulents caused dental microwear (Reinhard and Danielson 2005). Tsartsidou *et al*. (2006) examined a modern reference collection of plants in order to evaluate the contribution of phytoliths in archaeological studies in Greece. Webb and Longstaffe (2006) looked at oxygen isotope signatures in phytoliths for application in paleoclimate studies. Albert *et al.* (2006) and Bamford *et al.* (2006) constructed a taphonomical model based on the post-depositional preservation of grass, sedge, palm and dicotyledonous phytoliths from Plio-Pleistocene sediments at Olduvai Gorge in Tanzania. In a comparative study of modern phytoliths, a range of soil phytolith assemblages were analyzed from various phytogeographical zones from inter-tropical Africa to discriminate vegetation types (Barboni *et al.* 2007).

Grass silica short cells

The grass family (Poaceae) produces abundant silica bodies, especially within specific and specialized silica cells located in costal zones of the leaf epidermis (Metcalfe 1960; Kok 1972; Ellis 1979). In addition to being highly resistant to decomposition, grass phytoliths show markedly varied and distinct morphologies and several morphological studies have indicated that a number of grass morphotypes are characteristic of certain taxa (Twiss *et al*. 1969; Brown 1984; Mulholland 1989; Mulholland and Rapp 1992). Numerous types of silicification are found in grasses.

Silica infilling of intercellular spaces between sub-epidermal cells can also occur, including those from intercostal zones, but these atypical silica bodies are generally not characteristic in shape (Parry and Smithson 1964; Ellis 1979; Clayton and Renvoize 1986). Intracellular silicification of various types of epidermal cells, more often than not conforms closely to the shape of the original cell, and is sometimes very useful in palaeoecological studies (Bremond *et al.* 2005). This includes long cells, bulliform cells, stomatal guard cells, cork cells, macrohairs, microhairs and prickles (Ellis 1979).

Analyses of grass silica short cell (GSSC) phytoliths have been particularly forthcoming with regard to grassland history and associated palaeoclimatic changes, while complementing pollen studies in overall vegetative reconstructions (Figure 1). GSSC-phytoliths, are specialized silica cells (idioblasts) located in both the costal zone and intercostal zones of the leaf epidermis, overlying the vascular bundles and their associated sclerenchyma (Metcalfe 1960; Kok 1972; Ellis 1979; Clayton and Renvoize 1986). These cells comprise only a portion of the total siliceous residue and have restricted distributions within grasses, but they provide the most taxonomically useful types of grass phytoliths (Twiss *et al*. 1969, Rovner 1971, Ellis 1979; Brown 1984; Piperno 1988; Mulholland 1989; Mulholland and Rapp 1992; Fredlund and Tieszen 1997; Barboni *et al.* 1999; Stromberg 2002, 2004; Bremond *et al*. 2005).

Aims of the study

Palaeo-grassland inferences, using phytoliths, have been derived from quantitative assessments of phytolith assemblages using multivariate analyses and ratio models that provide indices to predict particular environmental conditions (Fredlund *et al*.

1985; Twiss 1992; Powers-Jones and Padmore 1993; Alexandre *et al*. 1997; Barboni *et al.* 1999, 2007; Fredlund and Tieszen 1997; Mercader *et al*. 2000; Boyd 2005; Bremond *et al.* 2008). However, the analysis of fossil phytolith assemblages tend be site-specific, and designed around specific taxonomic analogues in order to identify phytoliths that discriminate between different taxonomic groups (Stromberg 2004; Piperno 2006).

The original aim of this study involved a general approach for analyzing fossil phytoliths, but a lack of standardized methodology lead to a change of focus with the result that my endeavor culminated in the development of a uniform model for interpreting GSSC-phytolith assemblages within a singular ecological framework. The title of this thesis may therefore be misleading as this investigation eventually focused on establishing a standard methodology for fossil phytolith analyses and not on the analysis of fossil phytoliths from the central interior of southern Africa, itself.

My approach followed on previous phytolith studies that have emphasized the importance of studying modern phytolith assemblage variability in order to interpret fossil assemblages on a regional scale, through 'vegetative' rather than 'floristic' reconstructions of grass communities (Fredlund and Tieszen 1994; 1997). Reasons for using GSSC-phytoliths were based on three assumptions. Firstly, unlike many other phytolith-producing plant taxa, grasses occur in a variety of habitats throughout South Africa and are suitable indicators of a diversity of environmental conditions (Acocks 1988; Gibbs Russell *et al*. 1990). Secondly, studies have shown that, within the grass family, GSSC-phytoliths are proven to be highly diagnostic and hardy morphotypes (Twiss *et al.* 1969; Mulholland 1989; Fredlund and Tieszen 1994).

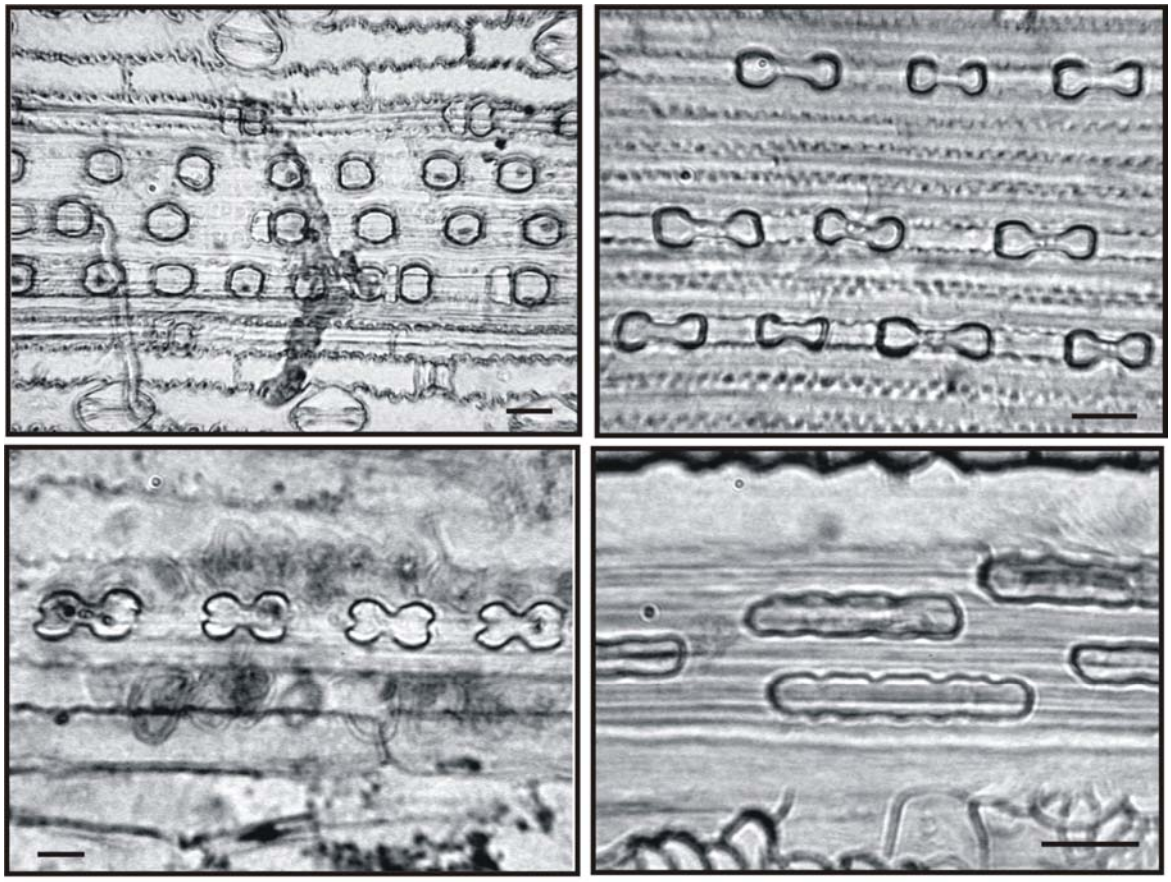

Figure 1. Photomicrographs of prepared grass leaf epidermis. Planar view of *in situ* short cell silica bodies within the leaf epidermis. The long axis of the leaf is horizontal. Scale = 10ų.

Thirdly, the effect of 'inheritance' on phytolith assemblages, where settling of phytolith assemblages in topsoils over time, is influenced by variables such as surface stability and chemical dissolution, (Fredlund and Tieszen 1994). As a result, interpretation of phytolith assemblages are complicated by several biases, including variable production rates of phytoliths in different plant groups, discrete size distributions in phytolith assemblages from different ecological contexts, post-depositional transport and variable preservation (Jones and Handreck 1963; Twiss *et al.* 1969; Bartoli

and Wilding 1980; Piperno 1988; Alexandre *et al.* 1997; Hansen *et al.* 1998). This inconsistent preservation of phytoliths owing to different taxonomic origins or morphology may strongly influence the interpretation of fossil phytolith assemblages (Jones and Handreck 1963; Bartoli and Wilding 1980).

An important effect as a result of these factors, together with the tendency for prolific grass phytolith production in general, is the tendency for grass phytoliths to be over-represented in soil assemblages (Piperno 1988). Focusing on phytoliths that are derived from a single plant group, circumvent potential bias related to differential preservation between different plant taxa. Additionally, grass phytolith assemblages provide abundant quantities of diagnostic GSSC-phytoliths.

Central to this study was the intention to refine the predictive power of GSSC-phytoliths by providing a quantitative model for predicting general patterns of past environmental conditions by interpreting morphologically diagnostic grass phytolith assemblages according to their association with the ecological requirements of the grass species that produces them, irrespective of taxonomic affiliation. An effort was therefore made to assign ecological meaning to GSSC-phytoliths by comparing a range of ecological preferences in modern grasses with the phytoliths that they produce, rather than just using phytoliths to discriminate between grass subfamilies, tribes or genera.

I attempted a methodology that is comparable to ecological structure analysis. Through this method, habitats and environmental conditions are reconstructed by conveying ecological attributes to extant organisms and comparing it to fossil communities (Andrews and Nesbit-Evans 1979; Van Couvering 1980; Andrews

1989; Reed 1997; 1998). These studies have shown that unlike methods using taxonomic analogues, the analysis of ecological association allows for the comparison of temporally or geographically diverse assemblages without being concerned with taxonomical differences. I subsequently devised a comparable method to explore and test the following assumption:

The biogeographical distribution of grasses in southern Africa, is linked to several climatic parameters (Vogel et al. 1978; Ellis et al. 1980; Gibbs Russell 1988; Gibbs Russell et al. 1990). Consequently, the morphology of South African grass short-cell phytoliths consistently follows meaningful environmental traits due to the relationship between phytolith shape and the ecological niche occupied by various taxonomic groups within the grass family. Grass short-cell phytoliths are therefore appropriate indicators of grass-community responses to periods of environmental change. This assumption forms the basis of the study and was tested through the following objectives in Chapters 3 and 4:

- Provision and explanation of a modern phytolith reference collection as a frame of reference for comparison;
- Assessment of the environmental significance of grass phytoliths, based on a botanical index of modern grass chorology, and using standard methods of observation, description and statistics to explore the relationship between grass short-cell morphology and grass chorology in southern Africa.

Structure of thesis

The remainder of the thesis is composed of seven chapters. Chapter 2 discusses methods and materials used for analyzing the ecological significance of modern

grass phytoliths. A description of grass short cell morphology, based on a modern reference collection that is included in two appendices, is presented in Chapter 3. Chapter 4 provides a quantitative analysis of the morphological data and the implications of these results are discussed and concluding remarks offered in Chapter 5. A list of references and appendices are presented in Chapters 6 and 7.

Methodology

Introduction

Assessment of the environmental significance of GSSC-phytoliths, was based on a botanical index of grass biogeography, extracted from a dataset of three hundred and nine grass species, comprising eight subfamilies, nineteen tribes and one hundred and two genera (Table 1). Morphological descriptions of the GSSC-phytoliths were guided by observations represented in two reference collections (Appendices 1 and 2). One collection consists of slide preparations of five-centimetre leaf sections taken from voucher specimens of mature individuals housed at the herbarium of the Department of Botany at the National Museum in Bloemfontein, the National Herbarium of Pretoria and the Bolus Herbarium at the University of Cape Town (Appendix 1). Standard dry-ashing procedures (described in Appendix 1) were followed to extract phytoliths from these herbarium samples (Parr *et al.* 2001). Additional comparisons were done on a collection of prepared slide vouchers of fully-articulated grass leaf epidermis sections from the Roger Ellis collection housed at the National Herbarium of Pretoria (Appendix 2) A set quantity of one hundred GSSC-bodies were counted per slide, each slide representing one species. This included the articulated short cell bodies located along the costal zones of each epidermis section from the Roger Ellis collection, and the disarticulated short cell bodies counted along randomly selected traverses in the dry-ashed collection.

Biogeographical data for each species was collated from published research, herbarium records and the National Herbarium Computerized Information System

(Chippendall and Crook 1976; Gibbs Russell 1985; Gibbs Russell *et al.* 1990). The latter is a robust vegetation database that includes distribution data of one thousand eight hundred and eleven species, based on the records of more than sixty-two thousand grass specimens collected in southern Africa. This system provides a checklist of grasses that occur in each of the 3900-quarter degree grids that cover southern Africa (Gibbs Russell 1985; 1988; Gibbs Russell *et al*. 1990).

As a first step, species were converted into numeric profiles, using eleven GSSC-morphotype variables to represent each species according to their rate of recurrence (presence or absence) into a binary indicator matrix (summarized in Table 3, listed in lefthand-column in Appendix 3). However, this quantification method produces only frequency data. As a result, the procedure was repeated by counting one hundred individual GSSC-phytoliths per slide to ascertain the relative abundance (rate of production) of each of the eleven morphotypes, in order to provide a dataset that could be tested for significant differences between means (ANOVA) (summarized in Table 4, listed in righthand-column in Appendix 3). A non-parametric Spearman's rank-order correlation-coefficient, r_S, was used to confirm expected positive covariation between the values of the corresponding GSSC-phytolith types in two phytolith datasets (Table 3 and 4) (see Quantitative Analysis).

From the data, I created GSSC-profiles for six subfamilies, as well as for nineteen ecological categories, their diversity reflected by photosynthesis, rainfall and habitat. The GSSC-morphotype variables were grouped into five categories, namely morphotype, subfamily, photosynthesis, rainfall and habitat. In order to eventually infer ecological trends from GSSC phytoliths, percentages of morphotypes were

calculated for each category, and in return, percentages of each adaptation, (i.e. morphotype), were analyzed by ecological category. This was achieved by tabulating the percentages of GSSC-phytoliths according to their distribution and the ecological adaptation of the grasses that produce them. The results are summarized in Table 5 and 6 and presented in Appendices 7, 9, 12 and 14.

Thus, each category was allocated a numerical profile based on morphotype association that reflects a non-phylogenetic community structure. This means that ecological preferences are differentiated based on the resulting phytolith assemblage structure. The approach allowed me to determine the degree of association between GSSC-morphotype and ecological condition, and enabled me to compare modern ecological categories directly with each other as well as with fossil phytolith assemblages because the parameters that were used are not taxon-specific and therefore not effected by temporal or geographical separation.

Description of Ecological Categories

Climate is perceived as the principal dynamic component and obvious independent variable shaping vegetation on all scales (Schulze 1997). South Africa, being the southernmost sovereign region on the African continent covers a total surface area of approximately 1,2 million square kilometers with the effect that its topography and latitudinal position (between 18º and 35º south) strongly influences general climate patterns (Figure 2). In addition, the country has an extensive coastline, constituting the western, southern and eastern boundaries of the country. Consequently, the effects of oceanic circulation systems and offshore currents are well reflected in the

overall climate distribution of the region (Deacon and Lancaster 1988; Scott 1995; Barrable *et al.* 2002; Scott and Lee Thorp 2004; Chase and Meadows 2007).

Since grasses are adapted to react relatively swiftly to environmental changes, including variation in atmospheric carbon dioxide, moisture availability and temperature, the taxonomic composition of grassy ecosystems indirectly reflects a variety of regional climatic conditions by means of their ecological preferences (Vogel *et al*. 1978; Gibbs Russell 1988, 1990; Ficken *et al*. 2002; Scott 2002; Wooller and Beuning 2002). Nineteen ecological preferences (categories) were selected, representing different biochemical variants of the photosynthetic pathway, rainfall variability and habitat preferences associated with grass distribution in South Africa.

Photosynthesis

Distribution of grasses in southern Africa is primarily linked to growing season temperature and seems to account for the geographic distribution of C_3 and C_4 grasses, where elevated temperatures during the growing season favour the C_4 photosynthetic pathway (Vogel *et al*. 1978; Ellis *et al.* 1980; Cerling *et. al*. 1997; Ehleringer *et al.* 1991, Ehleringer *et al.* 1997; Sage and Monson 1999; Sage 2004). C_3 and C_4 respectively refer to three-carbon and a four-carbon molecules being the first products in photosynthesis (Ehleringer and Monson 1993). They represent two photosynthetic pathways that exist among grasses - the ancestral C_3 (Calvin–Benson) photosynthetic pathway which is utilized by grasses generally thriving under cool, dry to mesic winter-rainfall conditions, and the C_4 (Hatch–Slack) photosynthetic pathway, which is subdivided into aspartate formers and malate formers (Vogel *et al*. 1978; Ellis *et al.* 1980; Schulze *et al*. 1996). The aspartate formers dominate grass

flora in arid summer rainfall regions with conditions of low soil moisture availability, while the malate formers (NADP-me type) attain their maximum frequency in high summer rainfall areas (Vogel *et al*. 1978; Ellis *et al.* 1980; Gibbs Russell *et al.* 1990) Two subtypes are recognized for the aspartate formers, namely the NAD-me-type, dominating in warm, arid areas with low and unpredictable summer rainfall and the PCK-type (phosphoenolpyruvate-carboxykinase), associated with grasses adapted to intermediate rainfall levels and occurring in moist habitats with summer rainfall less than 350mm per year, (Ellis *et al.* 1980). The PCK-type appears to be an intermediate between the NAD-me type and the malate forming NADP-me type (Ellis *et al.* 1980).

Rainfall

South Africa is part of a generally semi-arid subcontinent, with less than five percent of the region receiving annual rainfall of greater than 800 mm and more than ninety percent of rainfall returning to the atmosphere as part of evaporative loss (Schultz 1997). Although dry climates dominate southern Africa, the region covers a wide range of climatic zones, ranging from true desert to temperate and subtropical to tropical systems, with strongly seasonal precipitation regimes (Rutherford and Westfall 1994; Oldfield and Thompson 2004; Mucina and Rutherford 2006). The region's rainfall is determined by seasonal shifts of the South Atlantic and Indian Ocean anti-cyclonic, high-pressure systems (Deacon and Lancaster 1988). The northern and eastern parts of southern Africa receive mostly summer rainfall where the eastern escarpment with its Drakensberg range is responsible for major orographic effects. Mean annual precipitation is highest along the eastern

escarpment and generally decreases westwards from the escarpment across the plateau (Schulze 1997). Another rainfall maximum occurs in the southwestern Cape where rainfall increases from 400 mm on the Cape Flats to over 2000 mm in the Cape Fold Mountains (Deacon and Lancaster 1988). Eighty percent of the annual precipitation in the southwestern Cape occurs during the winter season (Schulze 1997; Rutherford and Westfall 1994).

Three rainfall subcategories were selected based on the arrangement of grass subfamily regions according to Gibbs Russell (1988) (Figure 2). The subcategories consists of a higher than forty percent winter rainfall group (>40%W), a less than five hundred millimeters summer rainfall group (<500mm S), and a higher than five hundred millimeters summer rainfall group (>500mm S). Distribution of grass subfamilies in southern Africa suggests that the Panicoideae subfamily is most abundant in summer rainfall areas with more than 500 mm of rainfall per year, while the Chloridoideae and Aristidoideae are most abundant in summer rainfall areas with rainfall less than 500 mm per year. This corresponds to the division between dry and moist grassland of the Grassland Biome where sour (unpalatable) andropogonoid grasses predominate above 600 mm of rainfall and sweet (palatable), chloridoid grasses are more common below 600 mm of rainfall (Rutherford and Westphall 1996). The Arundinoideae, Bambusoideae, Danthionoideae, Ehrhartoideae and introduced pooids prefer regions with more than forty percent of rainfall occurring in winter while indigenous pooids are most abundant in the high Drakensberg mountain range on the eastern escarpment (Gibss Russell *et al.* 1990).

Habitat

The South African region represents a highly diverse and endemic, southern temperate and subtropical flora, which is reflected by several distinctive ecological regions or biomes (Cowling and Hilton-Taylor 1997; Rutherford 1997; Mucina and Rutherford 2006) (Figure 2). Defined on the basis of climate, corresponding life-form patterns and vegetation structure, biomes offer an ecological framework for biotic communities, including grasses (Rutherford and Westfall 1994; Low and Rebelo 1996). Grasses occur ubiquitously throughout most of South Africa. It is the predominant plant life form in the Grassland Biome, and is, except for the Desert Biome, also widespread in all the major biomes of southern Africa (Rutherford and Westfall 1994; Rutherford 1997).

Twelve habitat subcategories were selected for the study (see Habitat category in Table 5). Except for edaphic and montane grasslands, and grasses adapted to shady habitats, description of habitat types was based on their association with seven well-defined biomes according to the categorization by Rutherford and Westfall (1994) and Rutherford (1997). These were the categories used by Gibbs Russell *et al*. (1990) in their reference guide of southern African grasses (Figure 2). The latest categorization of South African biomes includes all seven biomes described by Rutherford and Westfall (1994), but with the inclusion of two new biomes that were previously elements of the Savanna Biome, namely the Albany Thicket Biome and Indian Ocean Coastal Belt Biome (Rutherford *et al.* 2006a, Figure 2).

Strictly speaking, the term ‘grassland’ refers to vegetation dominated by grasses in a single layered structure or sometimes with an open, woody plant cover (Rutherford and Westfall 1994) Therefore, in describing the habitat categories, the term

'grassland' was used to refer only to montane, edaphic, and savanna grasslands and the grasslands of the Grassland Biome. In contrast, grass communities occurring in the Desert, Succulent Karoo and Nama-Karoo biomes make up a very small fraction of the total vegetation component and cannot be described as grasslands.

Grassland

One hundred and thirty four grass species from the sample group were associated with the Grassland Biome. The temperate grasslands of South Africa cover the high central plateau of South Africa, inland areas of Kwazulu-Natal and the mountainous regions of the Eastern Cape Province, occupying about 24 percent of the country's surface area (Rutherford and Westfall 1994; Mucina *et al.* 2006a). It is strongly seasonal with summer rainfall and late summer maximum in vegetation, followed by near complete termination of activity in winter accompanied by winter drought (O'Connor and Bredenkamp 1997). Thunderstorms and hail are common in summer and frost is common in winter, while fire is vital to its structure. Division between dry and moist grassland are made on the basis of annual rainfall, with 500 to 700 mm of rainfall marking the boundary (Rutherford and Westfall 1994) (Figure 2). Perennial grasses are the dominant plant form, but annuals are important components of the vegetation where disturbance occurs. The grasslands are moisture-dependant and decreases with lower annual rainfall. Woody species are limited to specialized niches, but forbs form an important component of the grasslands (Rutherford and Westfall 1994).

Montane and High altitude grassland

Eighty eight grass species from the sample group were associated with these grasslands. The montane grasslands of South Africa generally correspond to the

Grassland Biome in terms of their floristic composition, the obvious distinction pertaining to mountainous regions of generally high altitudes with relatively cool mean annual temperatures, where rainfall may occur at any time of the year and orographic mists supplement rainfall (Meadows and Linder 1993; Mucina *et al*. 2006a; Rutherford *et al.* 2006a). Two broadly defined sub-categories were delineated in this study: (1) montane grasslands that are primarily associated with the Great Escarpment of the Drakensberg region, including montane grassland communities on Karoo inselbergs, and the Cape Folded Belt in the southwestern and southern Cape; (2) high-altitude montane grasslands that are associated with the very highest plateaus and mountain ridges of the Drakensberg region found generally above 2000m above sea level (Figure 2). The high-altitude montane grasslands category mostly corresponds with Acocks' 'Themeda—Festuca Alpine' Veld (Acocks 1988), the 'Alti Mountain Grassland' of Low and Rebelo (1988) and the 'Drakensberg Afroalpine Heathland' Sub-biome of Mucina *et al*. (2006a). The majority of the centres of endemism recognized in the Grassland Biome are linked to high altitudes.

Savanna Grassland

One hundred and fifty seven grass species from the sample group were associated with the Savanna Biome. The Savanna Biome represents the southernmost extension of the largest biome in Africa and nearly encloses the temperate Grassland Biome where it grades into the Albany Thicket and Indian Ocean Coastal Belt Biomes (Rutherford *et al*. 2006b). Savannas are characterized by wooded subtropical grasslands, also called savanna woodland, shrub savanna or bushveld in many areas of the country. It accounts for almost 33 percent of the South African

landscape, does not occur at high altitude and is found mostly below 1500 m with temperatures generally higher than the adjacent Grassland Biome (Rutherford and Westfall 1994). The biome is characterized by seasonal rainfall with wet summer and dry winter periods. Development of the modern savanna is closely linked to the evolution of C_4 photosynthesis in grasses (Sage and Monson 1999; Sage 2004).

Nama-Karoo

Eighty five grass species from the sample group were associated with this biome. The Nama-Karoo covers most of the vast central plateau region of the Western and Northern Cape Provinces. It is an arid biome that forms an ecotone between the fynbos flora to the south, and the subtropical savanna in the north (Mucina *et al*. 2006b). Climate influence is continental, with low unreliable rainfall that mostly occurs in late summer. Summers are hot with a mean January maximum of > 30°C. Local endemism is very low with Asteraceae, Fabaceae and Poaceae the dominant plant families.

Desert

Twenty six grass species from the sample group were associated with this biome. The Desert Biome adjoins the western Atlantic seaboard, southern Angola, Namibia and within South Africa, stretches from the Atlantic coast along the Orange River inland towards the town of Pofadder in northern Bushmanland (Jurgens *et al*. 2006). It is defined by less than 70mm of annual rainfall in the easternmost parts and by sparse perennial vegetation of less than ten percent canopy cover (Jurgens *et al*. 2006). The southern margin of the biome is bordering on the temperate winter-rainfall region of the most arid parts of the Succulent Karoo Biome (Jurgens *et al*. 1997). A

small variety of grass species, with *Stipagrostis* the most common genus, occurs in this hyperarid region of low rainfall and high evapotranspiration rates.

Succulent Karoo

Forty six grass species from the sample group were associated with this biome. The Succulent Karoo Biome is a semi-desert region restricted to the year-round and winter rainfall with very high levels of summer aridity (Milton *et al.* 1997). Mean annual rainfall is low, varying between 100 mm and 200 mm with the overall biome average about 170 mm. The biome occurs mostly west of the western escarpment through the western belt of the Western Cape, inland towards the Little Karoo, and interfaces with the Fynbos Biome with which it shares its greatest floristic affinity (Mucina *et al.* 2006a). A high diversity of dwarf leaf-succulent shrubs dominates the vegetation, mainly represented by the Aizoaceae, Euphorbiaceae, Crassulaceae and succulent members of the Asteraceae.

Fynbos

One hundred and four grass species from the sample group were associated with the Fynbos Biome. It has dry and hot summers, associated with a high frequency of trade winds, and winter rainfall, which is brought on by the occurrence of westerly cyclonic fronts (Rutherford and Westfall 1994). Mean annual rainfall averaged over the total area of the biome is about 480 mm. The biome is situated almost exclusively in the south-western and southern parts of the Western Cape Province, and comprises three major vegetation complexes, namely fynbos, renosterveld and strandveld (Rebelo *et al*. 2006). Fynbos consist of an evergreen, fire-prone shrubland dominated by the Restionaceae family, and shrubs of the Ericaceae, Asteraceae, Rhamnaceae and Rutaceae families (Rebelo *et al*. 2006). Trees are rare and grasses comprise

a relatively small part of the biomass. Grassy fynbos occurs on soils of finer texture, higher nutrient levels and under conditions of less summer drought. Grasses also occur in renosterveld vegetation, which refers to *Elytropappus rhinocerotis*, the dominant plant in this complex (Rebelo *et al*. 2006). Strandveld vegetation is usually found close to the sea and consists of dense to closed shrublands dominated by sclerophyllous, broad-leaved shrubs (Rebelo *et al*. 2006).

Forest

Afrotemperate Forests are highly distinctive, but characterized by very small and patchy occurrences over the wetter parts of the winter- and summer-rainfall areas of the country (Mucina and Geldenhuys 2006). Fifteen grass species were associated with this category. Forests occur scattered along the eastern and southern margins of South Africa, with the majority smaller than one hundred hectares in size. Forests are characterized by vegetation dominated by evergreen trees and a large specific set of distinctive flora where graminoids are usually rare (Rutherford and Westfall 1994). Their distribution is mostly determined by high water availability and persists in areas with mean annual rainfall of more than 525 mm with strong winter rainfall, and more than 725 mm with summer rainfall, while orographic precipitation also plays a major role. (Mucina and Geldenhuys 2006).

Edaphic habitats

One hundred and three grass species from the sample group were associated with this subcategory. Edaphic grasslands are not related to any particular climatic region. For this subcategory, edaphic grasslands were determined largely by the condition of the substratum, in this case seasonally or permanently waterlogged soils. In terms of vegetation structure it is associated with seasonal pans, swamps, vleis or wetlands

(White 1983; habitat subcategories *Damp soils* and *Swamps / Vleis* in Table 5 and 6) and corresponds to the Inland Azonal Vegetation category of Mucina *et al.* (2006c).

Shady habitats

Forty three grass species were associated with this habitat preference. As with the edaphic grassland category, this habitat type is not related to any particular climatic region or regional vegetation structure. Unlike the Forest habitat subcategory, this preference was selected on the basis of grass adaptation to shady habitats that include open woodland or riparian canopy and rock crevices in open environments (Gibbs Russell *et al.*1990).

Classification of GSSC-morphotypes

Introduction

Globally, the grass family comprises about one third of the Earth's vegetative cover in terms of grass-dominated ecosystems, savannas and natural grasslands and is ecologically the most dominant and economically the most important plant family in the world (Gould 1968; Chapman 1996; Jacobs 1999; Kellogg 2001; Wooller and Beuning 2002; Piperno and Sues 2005). The grass family is the seventh largest plant family in southern Africa with 194 genera, and 967 species and infraspecific taxa, of which 115 are naturalized and 847 are indigenous, including 329 endemic taxa (Gibbs Russell 1985, 1986, 1987, 1988; Campbell and Kelogg 1987; Gibbs Russell *et al*. 1990). The Grass Phylogeny Working Group (GPWG 2001) recently reclassified the Poaceae into thirteen subfamilies, with eight subfamilies recognized in South Africa, *viz.* Aristidoideae Caro, Arundinoideae Burmeist., Bambusoideae Luerss., Chloridoideae Kunth ex Beilschm., Danthonioideae Barker & H.P.Linder, Ehrhartoideae Link, Panicoideae Link, Pooideae Benth. Classification of subfamilies in the Poaceae is based on a range of cytological and anatomical criteria. A number of anatomical characters indicate photosynthetic pathway with a single pathway that usually predominates in each subfamily (Clayton and Renvoize 1986; Gibbs Russell 1988; GPWG 2001).

Modern grass-dominated ecosystems cover more than fifty percent of southern Africa south of 22°S, a region that is also a transitional zone between tropical and temperate grasslands (Rutherford and Westfall 1994; Scott 2002). The biogeography

of grass communities in South Africa is primarily reflected on a taxonomic level (Gibbs Russell 1988). Of the eight subfamilies recognized by the GPWG (2001), occurring in southern Africa, five contain exclusively C3 species (Bambusoideae, Pooideae, Danthonioideae, Arundinoideae and Ehrhartoideae). The other three subfamilies include C_3, C_4 as well as C_3/C_4 intermediate species (Aristidoideae and Panicoideae), and almost exclusively C_4 species, except for *Eragrostis walterii* Pilg., and the danthonioid species *Merxmuellera rangei* (Pilg.) Conert (Chloridoideae) (Ellis 1984; GPWG 2001). The palaeoclimatic implications are therefore clear for South Africa, where the percentage frequencies of C_3 and C_4 grasses are significantly different in winter, summer and year-round rainfall regions (Vogel et al. 1978; Gibbs Russell 1988).

The Bambusoideae Luerss. is a C_3-subfamily with mostly perennial, tropical species confined to humid forest shade (Gibbs Russell *et al*. 1990; GPWG 2001). The C_3, Ehrhartoideae Link is annual or perennial and found in forests, open hillsides or aquatic habitats (Gibbs Russell *et al*. 1990; GPWG 2001). The C_3 Pooideae Benth. is annual or perennial and of cool temperate regions (GPWG 2001). In South Africa introduced species of the Pooideae are mainly confined to the winter rainfall region of the Fynbos Biome, while indigenous pooids are most abundant in the high Drakensberg mountains on the eastern escarpment (Gibbs Russell *et al.* 1990). Arundinoideae Burmeist. is generally regarded as a diverse, polyphyletic group, lacking reliable diagnostic features, that is mainly distributed throughout the Southern Hemisphere (Gould 1968; Ellis 1986). South African representatives of the Arundinoideae all follow the C_3 photosynthetic pathway and occupy a wide range

of niches, from aquatic species like *Elytrophorus* and *Phragmites,* to montane-adapted species like *Styppeiochloa* (Renvoize 1981; Gibbs Russell *et al*. 1990). The subfamily also has developed several structural adaptations to inhabit and survive in the Fynbos Biome (Linder and Ellis 1990). The Danthonioideae Barker & H.P.Linder, previously included in the Arundinoideae, is exclusively C_3, mostly perennial, and mainly found in mesic to xeric open habitats of the Fynbos, Succulent Karoo and Nama-Karoo Biomes (Ellis and Linder 1992; Gibbs Russell *et al*. 1990; GPWG 2001). The C_4 Aristidoideae Caro represents annual or perennial, mostly xerophytic species, that occur mainly in the Succulent Karoo, but also in the Desert, Nama-Karoo and Savanna Biomes (Gibbs Russell *et al*. 1990; GPWG 2001). The Panicoideae Link can generally be differentiated from other subfamilies by its spikelet characteristics (Ellis 1986). Species are annual or perennial, of the tropics and subtropics, but also diverse in temperate regions (Gibbs Russell *et al*. 1990; GPWG 2001). It is a large subfamily with South African genera incorporated into three tribes, the Andropogoneae Dumort, Arundinelleae Stapf, and Paniceae R. Br. The genus *Panicum* L. includes species exhibiting all five photosynthetic types known in the Poaceae – non-Kranz or C_3, C_3/C_4 intermediate and Kranz or C_4, which is further subdivided into NADP-me, PCK, and NAD-me subtypes (Ellis 1988). With the exception of the C_3 species *Eragrostis walteri* and *Merxmuellera rangei*, the Chloridoideae Kunth ex Beilschm. is regarded as a C_4-subfamily (Ellis 1984, Gibbs Russell 1988; GPWG 2001). Species are annual or perennial, and of dry climates, especially in the subtropical and temperate regions of the Savanna and Grassland Biomes (Gibbs Russell *et al*. 1990; GPWG 2001).

Morphological Description

Background

In a phylogenetic study of grasses Metcalfe (1960) recognized cubical, round, oblong, saddle-shaped, elongated, cross-shaped, dumbbell-shaped, and intermediate phytolith forms. Opal phytoliths from dust and soils were assigned to different grass vegetation types and it was recognized that there is a general difference in the phytolith morphology between short grasses and tall grasses (Suess 1966; Twiss *et al.* 1969). Suess (1966) divided the silica bodies in irregular and regular types in order to classify grassland regions, while Twiss *et al.* (1969) proposed a typological scheme for identifying grass subfamilies by dividing short cell phytoliths into four classes: a chloridoid class (saddle shapes); a panicoid class (dumbbell, cross shapes); a festucoid class (cubical, round, oblong shapes); and an informal "elongate" class. Rovner (1971) made a distinction between panicoid and poacoid phytoliths based on discrete morphological features. He incorporated chloridoid types identified by Twiss *et al*. (1969) into the panicoid class while his “poacoid” class was associated with Twiss’s festucoid class. Rovner (1983) also stated that the elongated type phytoliths are present in all the classes and have therefore no significant diagnostic value. Brown (1984) elaborated on terminology, description and class overlaps, and reiterated Rovner’s view that the correlation between phytoliths and grass taxa are more complex than previously thought. A fundamental concern related to phytolith production in living plants is the production of either a particular phytolith morphotype by many taxa, or a variety of morphotypes by one taxon. These circumstances, known respectively as redundancy and

multiplicity (Rovner 1983), drew attention to the importance of standardized analytical methods as well as the need for modern phytolith reference collections to assist in the interpretation of fossil phytoliths assemblages (Brown 1984; Piperno 1988; Mulholland 1989; Stromberg 2004). Subsequent studies concerning grass phytolith classification validated the basic pattern of short cell phytolith taxonomy initially proposed by Twiss *et al*. (1969) and expanded the framework for grass phytolith classification through modifications to the Twiss *et al.* scheme. Palmer (1976) provided a comparative study of fossil grass cuticles and a reference collection of modern grass epidermises from East Africa, using light microscopy and SEM. Brown (1984) developed a phytolith key based on one hundred and twelve grass species from the USA. Mulholland (1989) looked at phytolith shape frequencies in North Dakota grasses and classified short cell morphotypes into three broad groups. Lobate forms include bilobates and crosses and correspond with Twiss's Panicoid class (Twiss *et al*. 1969; Twiss 1992.) Rectangular and conical bodies were described as sinuates, rectangles and rondels, and correspond with Twiss's Pooid phytoliths (Twiss 1992). The description of Mulholland's saddle type is based on the concavo-convex outline of its cross-section and is equivalent to Twiss's Chloridoid class (Twiss *et al* 1969; Twiss 1992). Fredlund and Tieszen (1994) identified nine diagnostic short cell phytolith types, namely conical, keeled, pyramidal, crenate, S*tipa*-type, simple-lobate, panicoid-type, cross and saddle. They made several comparisons. The conical morphotype correspond with Mulholland's rondel type (Mulholland 1989). The keeled morphotype is also equivalent to Mulholland's rondel type as well as the elliptical and acicular types described by Twiss *et al.* (1969) The

pyramidal type is comparable to the rectangular and oblong types of Twiss *et al.* (1969), and the rectangular form described by Mulholland (1989). The crenate type is similar to Mulholland's sinuate type and the oblong sinuous type defined by Twiss *et al.* (1969). Morphology of the *Stipa*-type bilobate is based on the symmetry of its cross-section, which has been described as distinctly trapezoidal (Brown 1984). The cross, simple lobate, Panicoid type lobate and Other lobate categories are regarded as typically, but not exclusively produced by the Panicoid subfamily (Fredlund and Tieszen 1994). The saddle type is identical to that of Mulholland (1989) and Twiss (1992). In short, the results suggest that bilobate, polylobate and cross morphtypes are generally regarded as common in the Panicoideae subfamily, saddles are mainly produced by the Chloridoid subfamily, while the trapeziform, sinuate and rondel types are generally correlated with the Pooideae subfamily. More recent endeavors included methods to standardize the discipline with regards to identification, description and analytical methods (Madella *et al*. 2005).

GSSC-phytoliths analysed in this study

All phytoliths analysed in this study are the morphologically diagnostic silica bodies found in specialized silica short-cells (GSSC) that are located in both the costal zone and intercostal zones of the leaf epidermis (Metcalfe 1960). In conventional grass-taxonomical studies, silica bodies are normally described as seen in surface (planar) view within the epidermis (Metcalfe 1960; Kok 1972; Ellis 1979). However, for this study, descriptions were made on the basis of three-dimensional shape and two-dimensional outlines (Table 2), according to the guidelines provided by the International Code for Phytolith Nomenclature 1.0 (Madella *et al.* 2005). This included

studying both planar and transverse (side view) aspects of the phytolith types in order to interpret their three-dimensional appearances and distinctive two-dimensional characteristics (Twiss *et al.* 1969; Mulholland 1989; Fredlund and Tieszen 1994) (Figure 3 A). Here the procedure for phytolith description of Mulholland (1989) was followed (Figure 3). Short cell phytoliths were primarily described according to their abaxial / adaxial aspects, defined as the planar (surface) view or top view according to Mulholland (1989). The four sides connecting the planar aspect to the base of the silica body were described as side views for the long opposite faces, compared to end views for the short opposite faces. The figures are presented as composites of several photomicrographs (Figure 3 B, C).

GSSC-phytoliths are geometric variations of cubes, rectangular to cylindrical bodies, truncated cones or beveled pyramids (Mulholland 1989), but according to their most basic outlines in planar view, GSSC-phytoliths can be divided into three fundamental categories: lobate-shaped, saddle-shaped and trapeziform-shaped (Twiss 1992). Because of the effects of multiplicity and redundancy, an effort was made to classify the morphotypes in a simplified system, without considering any taxonomical affiliations. Thus, eleven morphotypes, identified as consistent occurrences in the GSSC-phytolith suite, were divided into a Lobate, Saddle and Trapeziform class. Each class corresponded to morphologically affiliated types that, as a group, form a transitional range of shape variation (Mulholland 1989). It has been suggested that the concavity in the outer surfaces of these morphotypes is not related to specific morphological characteristics, but rather to external factors like dehydration (Ellis 1979).

Lobate Class

The Lobate class is represented by morphotypes with trough-shaped outer surfaces, distinctive central portions and nodular structures, namely Bilobates, Polylobates and Crosses (Figure 4). The Bilobate is perhaps the most diagnostic GSSC-phytolith type. It consists of two lobes separated by a central portion of varying length and thickness, also referred to as a neck, shank, shaft or isthmus (Ellis 1979; Mulholland 1989). The planar surfaces and lateral walls of Bilobates are normally concave. In planar view, the terminal margins of the lobes are mostly rounded but occasionally displayed indentations. Three basic variants were recognized in this study, based on the dimensions of the central portion or neck between the lobes, and the outline symmetry of the planar surface.

Bilobate variant 1

The Variant 1 Bilobate has a comparatively elongated central portion (Figure 4, 1-2). The length of the central portion is defined as more than one third of total length of body. It possesses orbicular lobes that are symmetrical in planar view. It also has a lateral plane of symmetry with the length of central portion or shank equal or greater than one third of total length of body. This morphotype category includes the *Aristida* -type dumbbell described by Mulholland (1989) and Fredlund and Tieszen (1994) and corresponds to types 3c and 3e in Twiss *et al*. (1969) and Twiss (1992).

Bilobate variant 2

The Variant 2 Bilobate has a comparatively short central portion (Figure 4, 3 – 12). The length of the central portion is defined as equal or less than one third of total length of the body. The category includes Bilobates with orbicular to ovate lobes that are symmetrical in planar view. The side view presents a lateral plane of

symmetry. This morphotype is equivalent to the Panicoid and Chloridoid dumbbells in Mulholland (1989) and types 3b, 3d and 3f in Twiss *et al* (1969) and Twiss (1992).

This category also includes the *Stipa*-type Bilobate, a predominantly pooid morphotype, which appear trapezoidal or tabular in side view with generally ovate to scutiform lobes (Mulholland 1989; Fredlund and Tieszen 1994). This type is not exclusive to *Stipa* but is also produced by C_3-taxa, including *Chaetobromus involucratus, Schismus barbatus* and *Pennisetum glaucocladum* (Appendix 1).

Bilobate variant 3

The Variant 3 Bilobate is always asymmetrical in planar view with the length of its central portion less than one third of total length of body (Figure 4, 13 – 16). The side is either tabular or trapezoidal. This type is comparable to the irregular complex dumbbell recognized by Twiss *et al*. (1969) and the 'Other lobate' category in Fredlund and Tieszen (1994).

Polylobate

Polylobates have more than two lobes and distinctive central portions between the lobes to distinguish it from sinuate trapeziform short cells (Figure 4, 17 – 20). They have well-developed lateral planes of symmetry with tabular outlines in side view. It is equivalent to type 3i in Twiss *et al.* (1969).

Cross

Description of the Cross morphotype is follows Mulholland (1989). Crosses are usually equidimensional in planar view and are distinguished by the presence of four lobes that can range from symmetrical to irregular in shape (Figure 4, 21 – 26). Lobes can be rounded or pointy with a moderately defined central portion. This

category corresponds with type 3a in Twiss *et al.* (1969) and Twiss (1992).

Saddle Class

The Saddle class is represented by equidimensional bodies, also with concave outer surfaces, that are distinguished mainly by their planar outlines (Figure 5). Numerous types have been described. Brown (1984) listed eleven types and Thorn (2004a) described three kinds, a narrow base, wide base and tabular variant, based on the proximo-distal dimensions of the silica body. A diagnostic feature distinguishing Saddles from the Trapezoid type in the Trapeziform class, is its comparatively shorter proximo-distal length (Figure 6).

Saddle Variant 1

The body is trapezoidal in side view and exhibits a concave base and plateau that varies from square to rectangular in planar view. The base can widen or taper distally and is rarely vertical, thus including all three variants described by Thorn (2004a, 2004b). The plateau has rounded corners, with two or sometimes only one medially constricted margin (crescent-shaped), and two sides that are always moderately convex (Figure 6).

Saddle Variant 2

The body is trapezoidal in side view and exhibits a concave base and plateau that vary from square to rectangular in planar view. The plateau has rounded corners with no constricted margins (Figure 7). This category includes all three variants described by Thorn (2004).

Trapeziform Class

The Trapeziform class includes more heterogeneous morphotypes that are also

regarded as geometrically uncomplicated (Mulholland 1989) (Figure 8). Except for the Rondel, all the Trapeziform morphotypes exhibit quadrilateral dimensions in planar view. Definition of subcategories is based on constantly recurring morphological occurrences.

Trapezoid

Trapezoids are six-sided, square or rectangular silica bodies with few sides parallel. Planar margins are angular and not medially constricted (Figure 8, 1 – 12). The proximo-distal length of the silica body is generally longer compared to Saddle types. The Trapezoid category is equivalent to types 1b,1d and 1f in Twiss *et al* (1969), the rondel types described by Mulholland (1989), the conical and pyramidal types in Fredlund and Tieszen (1994) and rondel types g, h and i in Thorn (2004a).

Rondel

The Rondel is cylindrical or semi-cylindrical, tapers distally, and resembles a truncated cone (Mulholland 1989). It is circular, elliptical or acicular in planar view (Figure 8, 13 – 18). This morphotype compares to type 1a in Twiss *et al.* (1969) and the conical type in Fredlund and Tieszen (1994).

Oblong

The Oblong category includes six-sided silica bodies that are at least twice as long as broad with parallel or nearly parallel sides (Figure 8, 19 – 27). This category is defined as having smooth, sinuous or crenate planar edges and trapezoidal cross-sections. It corresponds with types 1c, 1g and 1h in Twiss *et al*. (1969), and the "longer forms with more polygonal cross-sections" in Mulholland (1989, p 495). This includes Mulholland's sinuate type which is comparable to the crenate types in

Fredlund and Tieszen (1994).

Reniform

The Reniform type is essentially a crescent-shaped Trapezoid with angular planar margins and one medially constricted edge (Figure 8, 28 – 31). This morpotype is comparable to type 1e in Twiss *et al.* (1969) and the rondel types in Mulholland (1989).

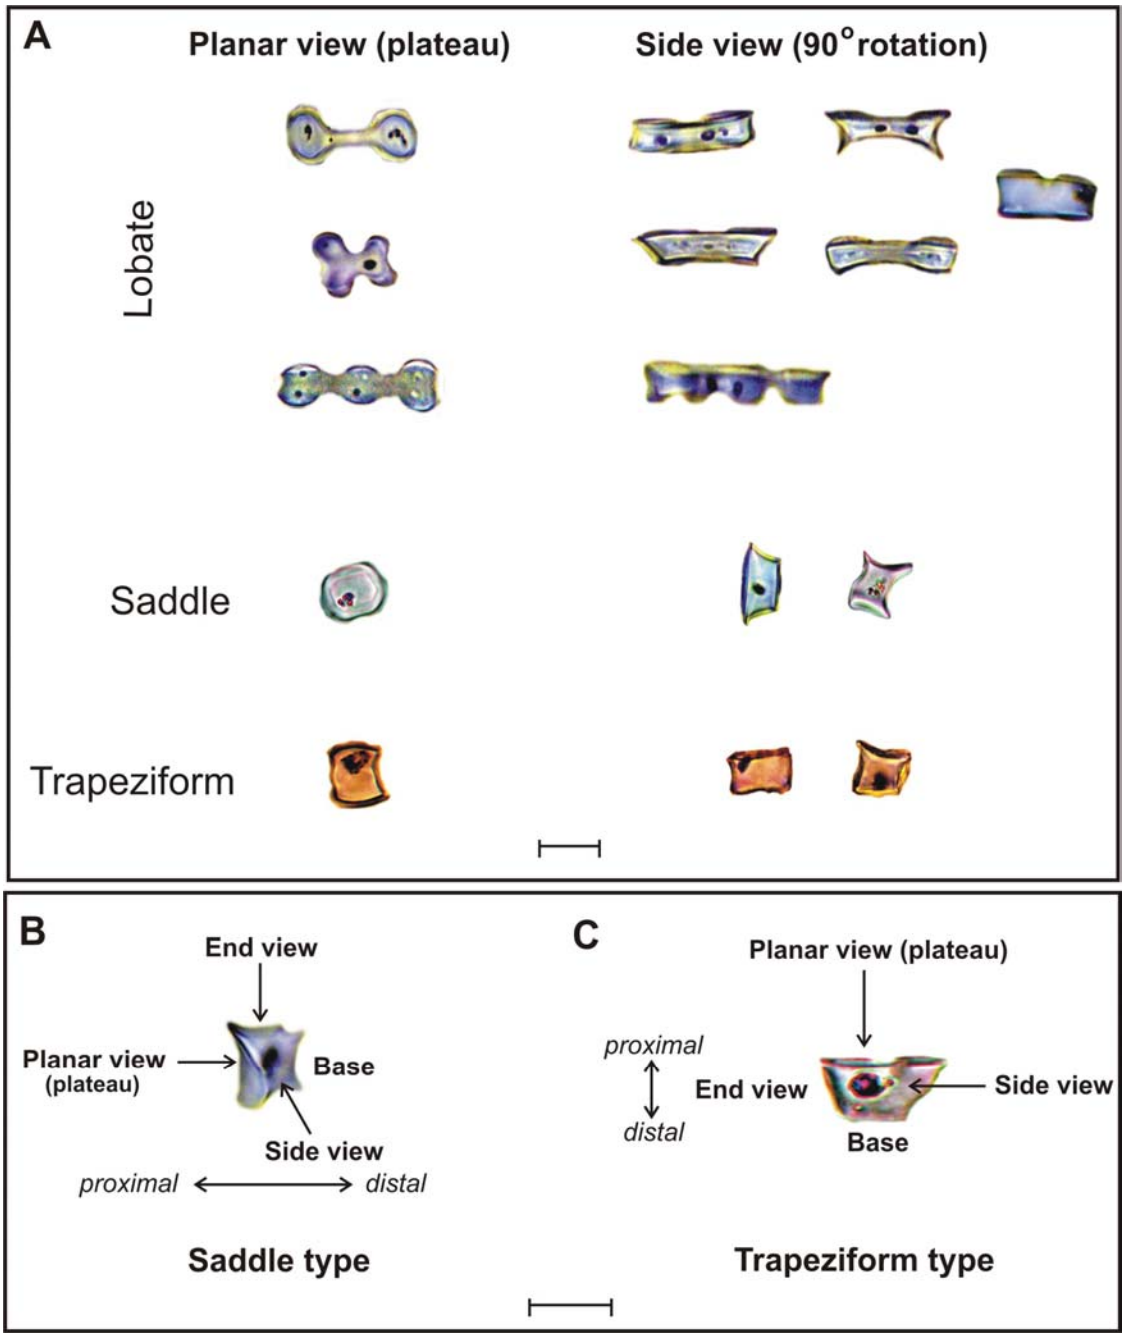

Figure 3. Orientation of short cell phytoliths. Abaxial / adaxial aspects, are defined as the planar view (surface or plateau) or top view (A) according to Mulholland (1989). The four sides connecting the planar aspect to the base of the silica body are described as side views for the long opposite faces, compared to end views for the short opposite faces (B,C).

Figure 4. The Lobate Class. Bilobate variant 1: (1) planar view; (2) side view. Bilobate variant 2: (3-7) planar view; (8-10) oblique view; (11-12) side view. Bilobate variant 3: (13-15) planar view; (16) oblique view. Polylobate: (17-18) planar view; (19-20) oblique view. Cross: (21-24) planar view; (25) side view; (26) oblique view. The so-called *Stipa*-type is represented by 7, 11-12 and 18.

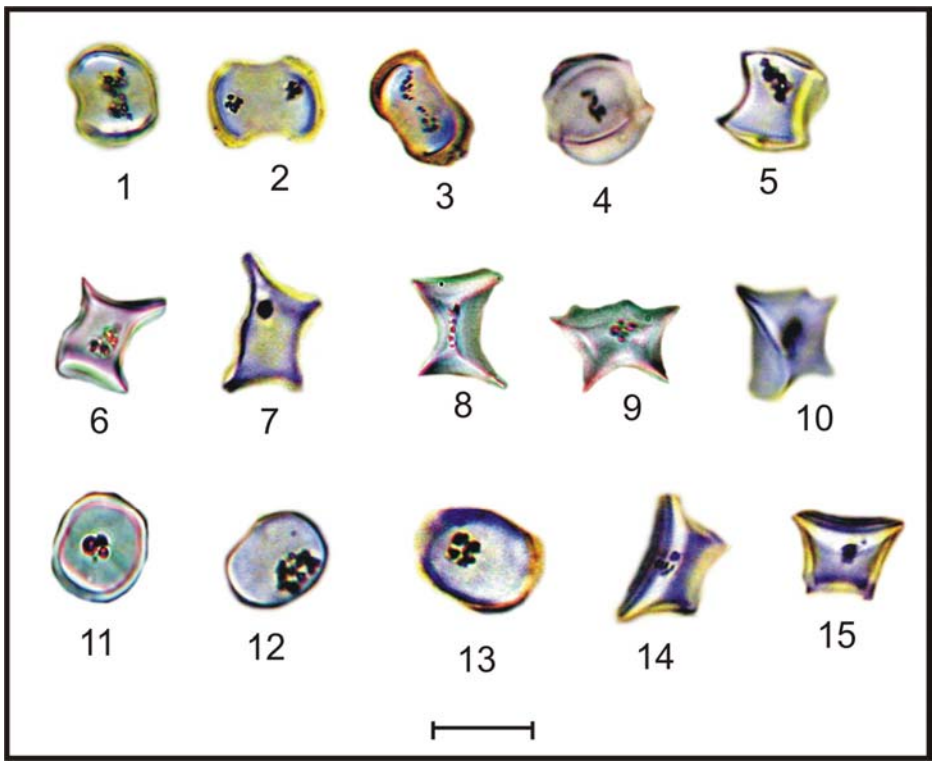

Figure 5. The Saddle Class. Saddle variant 1: (1-5) planar view; (6-8) side view; (9) end view; (10) oblique view. Saddle variant 2: (11-13) planar view; (14-15) side view.

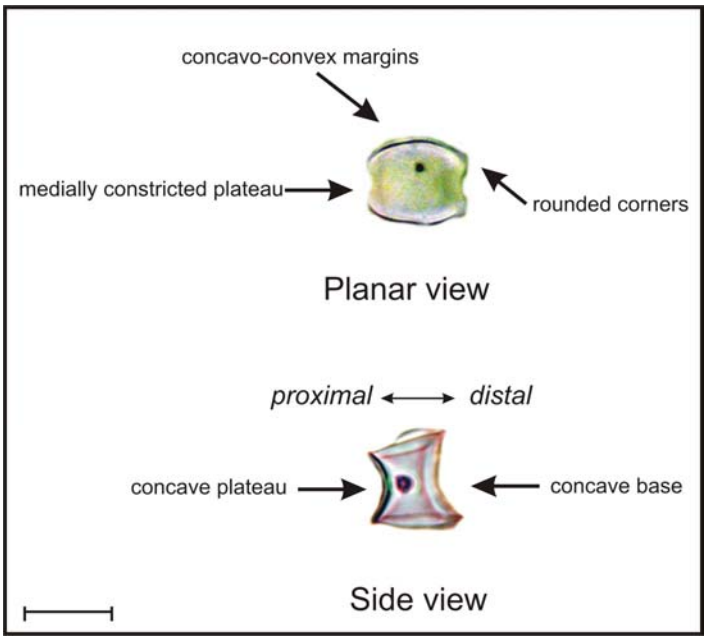

Figure 6. Distinguishing morphological features of the Saddle Variant 1.

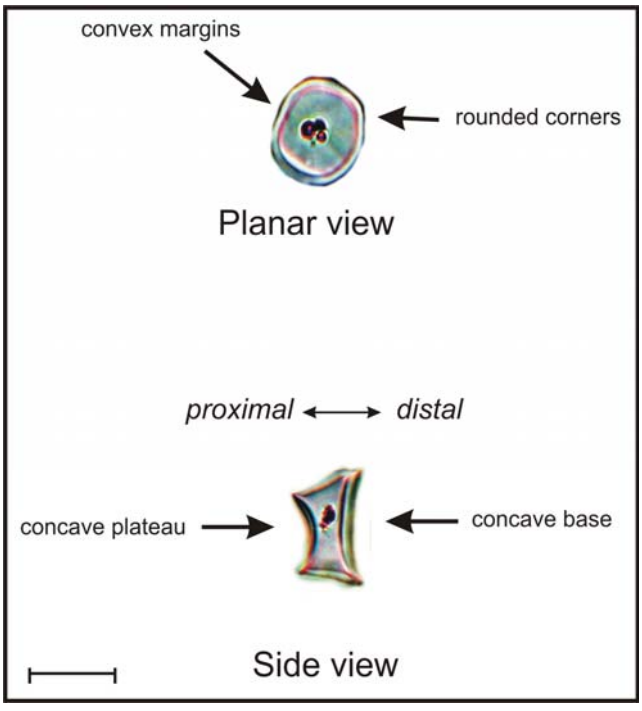

Figure 7. Distinguishing morphological features of the Saddle Variant 2.

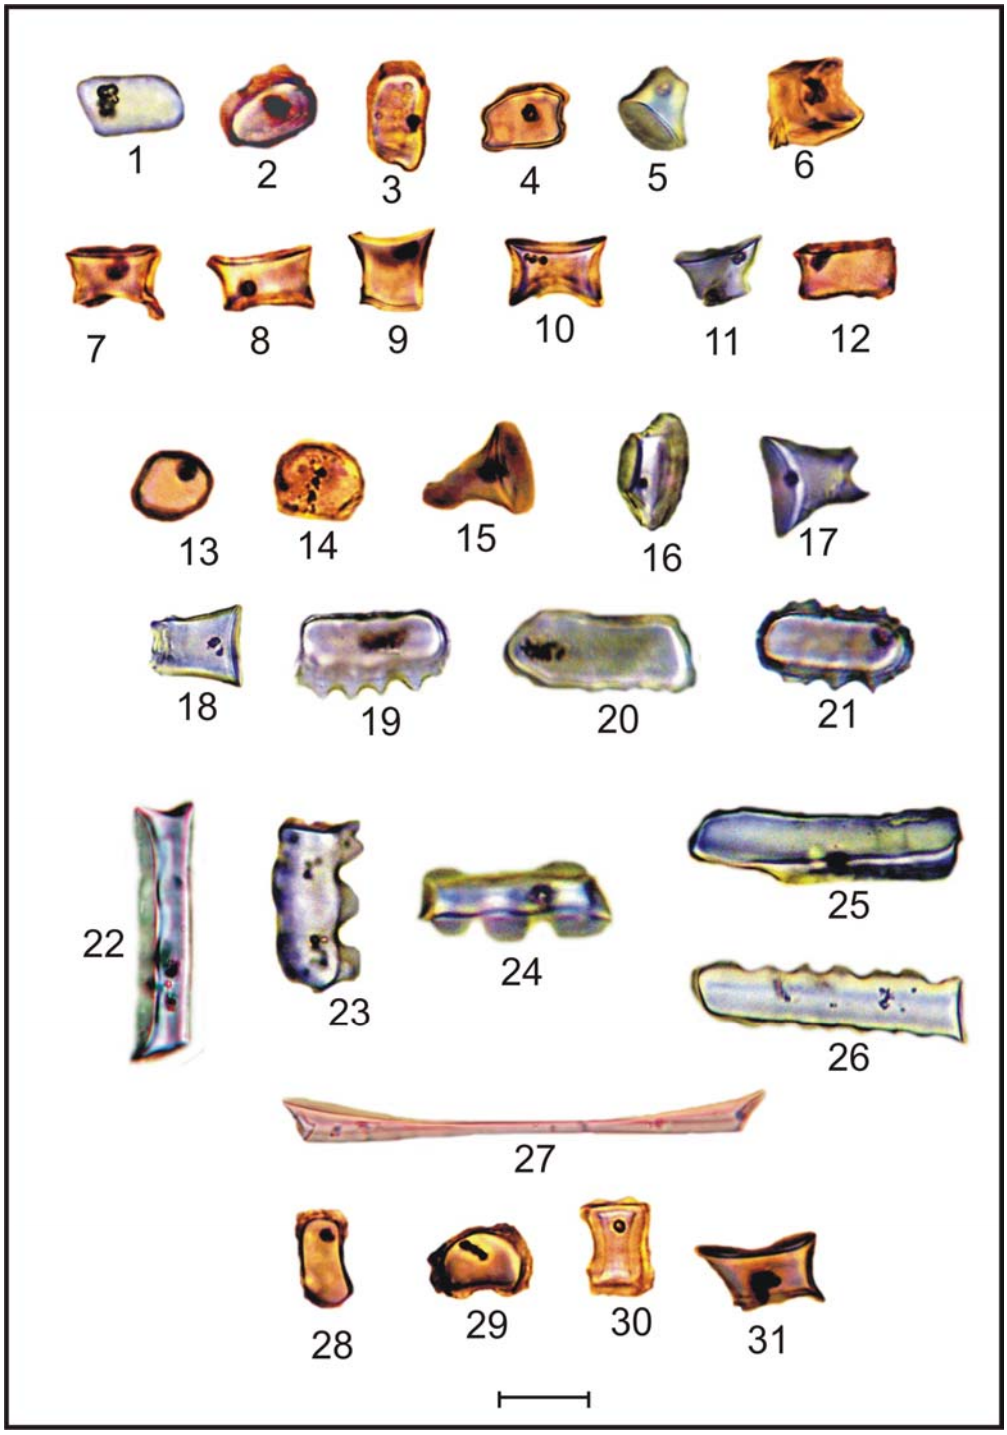

Figure 8. The Trapeziform Class. Trapezoid: (1-4) planar view; (5-6) oblique view; (7-12) side view. Rondel: (13-14) planar view; (15-17) oblique view; (18) side view. Oblong: trapeziform sinuate, (19-21,26) planar view; trapeziform smooth, (22, 25, 27) oblique view; trapeziform polylobate, (23, 24) oblique view; Reniform: (28-30) planar view; (31) side view.

Quantitative analyses

Introduction

The degree of association between eleven GSSC-phytolith morphotypes, according to their association with each other, their association at subfamily level, and their correspondence with ecological adaptations of the grasses that produce them, was evaluated with several statistical techniques in STATISTICA 7.0, using the StatSoft, 2005 software package. Trends in the *association through recurrence* or frequency (Table 3 and 5), and *association based on relative abundance* (Table 4 and 6), between GSSC-morphotypes and between GSSC-morphotypes and subcategories, were recorded and explored with one-way ANOVA tests and ordination using correspondence analysis.

Analysis of variance

Potential significance of differences in the *relative abundance of* GSSC-morphotypes in grass species (Table 4 and 6) was investigated using analyses of variance (one-way ANOVA tests). This was accomplished by comparing the number of GSSC-phytoliths calculated from the grass epidermal slides, in a one-way ANOVA to test significant differences of each morphotype within the categories, subfamily, photosynthesis, rainfall and habitat. Each ANOVA test was further analyzed with Tukey's post hoc Honestly Significantly Different (HSD) test for uneven sample sizes between pairs of subcategories for each morphotype.

Correspondence Analysis

The results were analyzed and illustrated with Correspondence Analysis (CA). Six

sets of CA were performed, one for each category. CA included only the morphotypes identified in the ANOVA and subsequent Tukey's HSD tests, which significantly differentiate between subcategories. The level of significance was restricted by using only those morphotypes found to significantly separate a third or more subcategory pairs in the one-way ANOVA.

CA is a multivariate ordination technique that identifies underlying similarities within specifically constructed datasets, just as principal components account for maximum variance between datasets (Greenacre 1984). CA is a suitable ordination technique in dealing with nonlinear data. For comparison and classification in this study, CA displays different communities along axes, so that communities that resemble each other the most on the basis of phytolith composition are grouped closer together. Presented in table form, the relationships between column and row data are explored simultaneously, with no prior causal relationship inferred between row and column data. For graphical display, two dimensions are used to give a reduced rank approximation to the data, even though it identifies the lines of best fit within a multidimensional cloud of data points (STATISTICA 7.0 Statistics Manual). When plotted on two dimensions, the subcategories that fall closest together are most similar in terms of their morphotype association. Morphotypes are also plotted, with subcategories falling closest to them most affected by their inertia (contribution to variation).

Results

A non-parametric Spearman's rank-order correlation-coefficient, r_S, was used to test the relationship between *GSSC-morphotype association through rate of recurrence*

(Table 3) and *GSSC-morphotype association through relative abundance* (Table 4). This was carried out with the consideration of the null hypothesis that no real association exists between *GSSC-morphotype association through rate of recurrence* and the *relative abundance of GSSC-morphotypes*. Results showed a highly significant linear relationship with positive covariation between the two datasets, which suggests that for each morphotype, frequency values accompany relative abundance values (Table 7, Appendix 4).

Association between Morphotypes

The results of the analysis of association between morphotypes through rate of recurrence are summarized in Table 3. The Variant 1 Bilobate recurred in 23.5% of species that produce the Polylobate (n = 51), but was not found in species that produce the Variant 2 saddle (n = 46), Trapezoid (n = 70), Rondel (n = 24) and Oblong (n = 26) morphotype. The Variant 2 Bilobate recurred in over 70% of species that produce the Variant 3 Bilobate (n = 40), Polylobate (n= 51) and Cross (n = 25) morphotype. Between 20% and 30% of species that generate the Trapezoid (n = 70), Rondel (n= 24) and Oblong (n = 26) morphotypes, also produce the Variant 2 bilobate. Variant 3 Bilobates were not found in species that produce the Variant 2 Saddle (n = 46). The Polylobate was absent in species that produce the Saddle and Rondel morphotypes, but respectively occurred in 26.9% (n = 52), 24.5% (n = 139) and 26.9% (n = 26) of species that generate the Variant 1, Variant 2 Bilobate and Oblong morphotype. The Cross was restricted to Lobate-morphotype producing grasses, and recorded in 15.8% (n = 139) of species that generate the Variant 2 Bilobate and 15% (n = 40) of species that produce the Variant 3 bilobate. The

Saddles were inclined to group together, with the Variant 1 type occurring in 43% (n = 49) of species that produce the Variant 2 Saddle, while the latter was found in 34.7% of species that generate the Variant 1 Saddle. Otherwise, the Variant 1 Saddle was restricted in its association by occurring in only 1.9% of the producers of the Variant 1 Bilobate (n = 52) and in 2.7% (n = 37) of species that produce Reniform morphotypes. The Variant 2 Saddle respectively occurred in 25% and 27% of species that produce the Rondel (n = 24) and Reniform (n = 37) morphotype, but was absent in producers of Cross and Oblong morphotypes. The Trapezoid morphotype was recorded in 62.5% (n = 24) of Rondel-producing species, 53.8% (n = 26) of Oblong producers and 73% (n = 37) of species that generate the Reniform morphotype.

Several trends were observed when the relative abundance of GSSC-phytoliths was calculated for each morphotype and compared with each other in a one-way ANOVA (Table 4, Appendix 6). There is no significant correlation between *relative abundance* and sample size (r = 0.4070, p = 0.2241), indicating that the proportional representation of GSSC-morphotypes were not influenced by differences in sample size (Figure 9). The results showed that the 1st and 2nd Bilobate Variant, as well as the Variant 1 Saddle, was produced in higher quantities compared to the rest of the morphotypes (Figure 10). The Bilobate Variant 1 accounted for 73% of all the morphotypes in the species that produce them (s.e. = 4.37; n = 52), the Variant 2 Bilobate nearly 70% (s.e. =2.51; n = 139), and 85% for the Variant 1 Saddle (s.e. = 3.02; n = 48). Grasses that generate the Variant 3 Bilobate, Polylobate and Cross, tend to produce more quantities of the Variant 2 Bilobates. As a result, representation of the Variant 3 Bilobate, Polylobate and Cross morphotypes by the species that

produce them, were comparatively low (Figure 10). In contrast, the Variant 3 Bilobate, Polylobate and Cross contributed only about 17% of the total number of morphotypes produced by grasses that generate the Variant 2 Bilobate. This suggests a possibly meaningful, but one-way association between the Variant 3 Bilobate, Polylobate and Cross morphotypes and the Variant 2 Bilobate. The Variant 2 Saddle accounted for 50% (n = 46) of all the GSSC-morphotypes by the species that produce them. Variant 2 Saddle producers also generated the Variant 1 Saddle (28%, s.e. = 5.53), and most of the Trapeziform morphotypes (21%), but almost no Lobate morphotypes (0.8%, s.e. = 0.65). The Trapeziform class of morphotypes is produced by grasses that also tend to frequently generate the Variant 2 Bilobate, albeit in comparatively low quantities. The Trapezoid morphotype represented 46% (s.e. = 3.63, n = 70) of the total number of morphotypes in the species that produce them. The rest were mostly made up of the Variant 2 Bilobate (11.76%), Rondel (9.34%), Oblong (10.41%) and the Reniform (15.42%). The Variant 1 Bilobate, Cross and Variant 1 Saddle were not produced by these grasses. Grasses that produce the Rondel (40%, s.e. = 6.86, n = 24), also generated comparatively high amounts of Trapezoid morphotypes (36.5%). The Oblong accounted for 59.0% of all the GSSC-morphotypes in the species that produce them (s.e. = 6.83; n = 26). Cross and Saddle morphotypes were absent in the Oblong producers. The Reniform morphotype accounted for only 29% (s.e. = 3.75, n = 37) of the morphotypes epresentation (quality ≥ 0.767). Almost 27% of the total inertia (Dimension 1) is driven by the difference in association between Lobate and non-Lobate morphotypes and in the species that produce them, with 38% (s.e. = 5.12) made up of Trapezoid

morphotypes.

One-way ANOVA of the relative abundance of GSSC-morphotypes phytoliths in the Morphotype dataset (Table 4) demonstrated that the proportional representation of each phytolith morphotype is significantly different ($p < 0.05$) among the eleven subcategories (Table 8, Appendix 6).

The first CA, which was carried out using the morphotypes found to be significant in the ANOVA, resulted in two dimensions explaining a cumulative 48.94% of inertia with a total of ten dimensions extracted (Table 9, Fig 11). The structure of the relationships indicated clustering of the Lobate, Saddle and Trapeziform morphotype classes, marked by the Variant 1 Saddle and Trapezoid morphotypes and reflecting the highest quality of 22% (Dimension 2) by a difference in association between Trapeziform and non-Trapeziform morphotypes.

Association between Morphotype and Subfamily

The association between GSSC-morphotypes and six different subfamilies based on morphotype rate of recurrence are summarized in Table 5. The Variant 1 Bilobate was recorded in at least 30% of Aristidoid (n = 29) and Panicoid species (n = 104). This concurs with the observation that the long-necked type is prevalent in the C_4, arid-adapted *Aristida* genus (Mulholland 1989; Gibbs Russell *et al.* 1991). The Variant 2 Bilobate is even more common, being recorded in all six subfamilies, but occurring more frequently in the Danthionoideae (53% of species, n = 65), the Ehrhartoideae (72% of species, n = 18) and the Panicoideae (74% of species, n = 104), It occurs less frequently in the Aristidoideae (10% of species, n = 29) and Chloridoideae (16% of species, n = 62). Occurrence of the Variant 3 Bilobate is

highest among the Danthionoideae (24% of species, n = 65) and Ehrhartoideae (27% of species, n = 18). The Polylobate is uncommon in the Aristidoideae and Chloridoideae, but prevalent in the Panicoideae (31% of species, n = 104) and the Pooideae (25%, n = 31). The Cross is primarily produced in the Panicoideae (19%, n = 104). Out of the eleven morphotype categories, the Variant 1 Saddle is probably the most selective morphotype, occurring only in the Aristidoideae (13% of species, n = 29) and Chloridoideae (78% of species, n = 62). This trend is more or less similar for the Variant 2 Saddle, which also occur almost exclusively in the Aristidoideae (72% of species, n = 29) and Chloridoideae (24% of species, n = 62). The Trapezoid is not found in the Chloridoideae, but common in the Danthionoideae (40% of species, n = 65) and Ehrhartoideae (55% of species, n = 18) and Pooideae (54% of species, n = 31). The Rondel is absent in the Chloridoideae and Panicoideae. More than 70% of species belonging to the Pooideae, and 22% of species belonging to the Ehrhartoideae subfamily (n = 31) were found to produce the Oblong morphotype. The Reniform is mainly produced by the Danthionoideae (33% of species, n = 65) and Ehrhartoideae subfamilies (33% of species, n = 18).

The relative abundance of GSSC-phytoliths calculated for each Subfamily subcategory is provided in Appendix 7 and summarized in Table 6. The long-necked Variant 1 Bilobate represented more than 20% of the total number of morphotypes counted in the Aristidoideae (s.e. = 8.08, n = 29) and Panicoideae (s.e. = 3.52, n = 102). The Variant 2 Bilobate represented 40.6%, of the total number of morphotypes counted in the Danthionoideae (s.e. = 5.22, n = 65), 37.5% in the Ehrhartoideae (s.e. = 7.67, n = 18) and 53.7% in the Panicoideae (s.e. = 4.04, n = 102). Despite their low

values, the Variant 3 Bilobate and Polylobate respectively represented the highest count in the Ehrhartoideae (10.6%, s.e = 5.03, n = 18) and Panicoideae (11.4%, s.e = 2.40, n = 104). The Cross morphotype was mainly produced by the Panicoideae (6.8%, s.e. = 1.64, n = 104). The two Saddle variants respectively represent 69.9% and 59.8% of the total number of morphotypes counted in the Chloridoideae (s.e. = 5.03, n = 62) and Aristidoideae (s.e. = 8.12, n = 29). The Trapezoid morphotype was relatively abundant in the Danthionioideae (23.9%, s.e. = 3.97, n = 65), Ehrhartoideae (26.5%, s.e. = 6.52, n = 18) and Pooideae (22.4%, s.e. = 5.17, n = 31), but the Oblong represented 43.8% of the total number of morphotypes counted in the Pooideae (s.e. = 7.55, n = 31).

One-way ANOVA indicated that only the Variant 3 Bilobate (p = 0.2381) was not significantly different between the six subfamilies included in the study (Table 10). The Tukey's HSD tests also showed that the Polylobate was not significantly different among a third or more subcategory pairs (Appendix 8). These two morphotypes were left out of the subsequent CA. The Tukey's HSD tests further indicated that the Aristidoideae subfamily were the most often significantly differentiated in terms of Variant 1 Bilobate, Variant 2 Bilobate and Variant 2 Saddle representation (Appendix 8). The Chloridoideae subfamily was the most often significantly differentiated by the Variant 1 Saddle. The Danthionoideae was most frequently different from other subfamilies in terms of the Variant 2 Bilobate, Rondel and Reniform morphotypes. Trapezoids and Rondels most frequently discriminated between the Ehrhartoideae and the rest of the subfamilies. The Panicoideae subfamily was the most often significantly differentiated by the Cross, the Variant 1 and Variant 2 Bilobate, while

the Pooideae was most frequently differentiated by the Trapezoid and Oblong morphotypes. Overall, the two Saddle variants, the Trapezoid and the Oblong provided the most differences between subcategory pairs.

The second CA, which was carried out using only those morphotypes found to be significant in the ANOVA test for the Subfamily -subcategories, show two dimensions that explain a cumulative 71.71% of inertia, with a maximum of five dimensions that can be extracted to reconstruct the frequency table (Table 11, Eigenvalues). As expected, those variables found to be significantly different between the most subfamilies delivered the highest contribution to total relative inertia, such as the Variant 1 Saddle morphotype (Table 11, Column coordinates). The association between subfamily and morphotype was plotted on the first two dimensions in Figure 12 and confirmed by maximum row percentage values (Table 11, Percentages of row totals). The Variant 1 Bilobate affiliated strongly with Aristidoideae (25.0%), the Variant 2 Bilobate with Panicoideae (62.5%), the Variant 1 Saddle with Chloridoideae (72.9%), the Trapezoid morphotype with Ehrhartoideae (30.4%) and the Oblong morphotype with Pooideae (49.7%). Inertia created by the matrix provided a first dimension that accounted for 48.93%, and a second dimension that accounted for 22.78% of the total inertia (Figure 12). The first dimension correspond to a C_4 / C_3 - gradient , with the two Saddle Variants representing predominantly C_4 subfamilies on the left side of the plot (positive values) and the Rondel, Trapezoid and Oblong morphotypes representing predominantly C_3 subfamilies on the right side of the plot (negative values).

Ecological Categories

Association between Morphotype and Photosynthetic pathway

Association between GSSC-phytoliths through their rate of recurrence (Table 5) indicated that the Variant 1 Bilobate mainly recur in the NADP-subcategory (37% of species, n = 28) and least in the C_3-subcategory (3% of species, n = 127). Recurrence of the Variant 2 Bilobate was comparatively frequent in the C_3- (28% of species, n = 127), NAD- (20% of species, n = 42) and PCK-subcategory (29% of species, n = 16), but very common in the NADP-subcategory (69% of species, n = 28). Recurrence of the Variant 3 Bilobate and Cross morphotype however, was generally low among all the subcategories (≤ 16% of species). The Polylobate persisted mainly in the NADP-subcategory (22% of species, n = 28) compared to the other subcategories (≤ 11% of species). The Variant 1 Saddle was significantly absent from the C_3-subcategory, extremely rare in the NADP-subcategory, and predominant in the NAD- (54% of species, n = 42) and PCK-subcategories (55% of species, n = 16). Recurrence of the Variant 2 Saddle was also very high in the NAD- (43% of species, n = 42) and PCK-subcategories (22% of species, n = 16) and rare in the C3- and NADP-subcategories. The Trapezoid and Reniform morphotype respectively persisted in 22% and 17% of species in the C_3-subcategory (n = 127), but in less than 8% in the rest of the subcategories. Recurrence of the Rondel and Oblong morphotypes was generally low among all the subcategories (≤ 10% of species).

The relative abundance reflected by GSSC-phytoliths in the Photosynthesis-category (Table 6, Appendix 9) showed that the Variant 1 Bilobate and Trapezoid morphotypes

respectively represented 30.8% (s.e. = 3.38, n = 127) and 23.6% (s.e. = 2.78, n = 127) of the total number of morphotypes counted in the C_3-subcategory. The Saddle Variant 1 (43.0%, s.e. = 7.06, n = 42) and Variant 2 (35.9%, s.e. = 2.20, n = 42) made the the biggest contribution to the NAD-subcategory. Trapeziform-class morphotypes were significantly absent in this subcategory. The Variant 2 Bilobate represented 55.3% (s.e. = 8.01, n = 28), and the Variant 1 Bilobate 25.5% (s.e. = 7.31, n = 28) of the total number of morphotypes counted in the NADP-subcategory. All the Saddle- and Variant 1 Saddle represented 43.0% (s.e. = 11.50, n = 16), and Variant 2 Bilobate 20.8% (s.e. = 9.06, n = 16) of the total number of morphotypes counted in the PCK-subcategory. The Trapeziform-class morphotypes were not represented in this subcategory.

A bivariate plot of the relative abundance of morphotypes with mean carbon isotope ratios, shows clear variation in $\delta\ ^{13}C$ values along a morphological gradient ranging from predominantly C_3 Trapeziform class morphotypes to predominantly C_4 Lobate and Saddle morphotypes (Table 12, Figure 13). The one-way ANOVA for the Photosynthetic pathway-category, including both C_3 and C_4 subcategories revealed that the Variant 3 Bilobate ($p = 0.28630$) is not significantly different between subcategories (Table 13). The Tukey's HSD tests also indicated that the Cross and Rondel morphotypes is not significantly different between a third or more subcategory pairs (Appendix 10). The C_3-subcategory was the most frequently differentiated by the Trapezoid and Oblong morphotypes, the NAD-subcategory by the Variant 2 Saddle, the PCK-subcategory by the Variant 1 Saddle, and the NADP-subcategory by Bilobate Variants 1 and 2 (Appendix 10).

By not including the Variant 3 Bilobate, Cross and Rondel morphotype, the third CA resulted in two dimensions explaining a cumulative 96.98% of total inertia, with a maximum of three dimensions extracted, and thus reflecting the use of only significant morphotypes (Table 14, Eigenvalues). The two-dimensional solution represented the row and column points very well (quality for all points ≥ 0.824). Contributions to the highest relative inertia were provided by the morphotypes found to be significantly different between the most subcategories, namely the Variant 1 and 2 Saddle and Trapezoid morphotypes (Table 14, Column coordinates). The association between the Photosynthetic pathway -category and the remaining GSSC-morphotypes was plotted on the first two dimensions (Figure 14). Maximum row percentage values indicated close alliances between the NADP-subcategory and the Variant 1 (27.5%) and Variant 2 Bilobate (59.8%), while the Variant 1 Saddle associated strongly with the NAD- and PCK-subcategories (Table 14, Percentages of row totals). The Variant 2 Saddle and Trapeziform morphotypes were mainly affiliated with the NAD- and C_3-subcategories (37.2% and 27.7%, respectively). The first dimension in the CA accounts for 60.69% of the total inertia and clearly represents a temperature gradient, with mild to cooler growing conditions represented by Bilobate Variant 1 and 2 and the trapeziform morphotype (positive values), and warm to hot growing conditions, represented by the two Saddle Variants (negative values). The second dimension (36.30% of total inertia) reflects differences between photosynthetic pathways, with primarily C_4 grasses represented by the two Bilobate and Saddle Variants (positive values), and predominantly C_3 grasses represented by the Trapeziform, Oblong and Reniform morphotypes (negative values).

One-way ANOVA conducted for the Photosynthetic pathway category using only C_4 subtypes, expectedly revealed that the Variant 3 Bilobate, as well as the morphotypes corresponding with the C_3-subcategory in the preceding CA, are not significantly different between subcategory pairs. In addition, the Tukey's HSD test singled out the Cross morphotype as not significantly different between subcategory pairs (Appendix 11).

As a result the fourth CA offered two dimensions explaining a cumulative 100% of inertia (Table 16, Eigenvalues) and consequently, the two-dimensional solution represented the row and column points very well (quality for all points = 1.0). Contributions to the highest relative inertia (≥ 0.242) were provided by the Variant 1 and 2 Saddle (Table 16, Column coordinates). The first dimension accounts for 95.40% of the inertia and represents a biochemical gradient in grasses between aspartate formers (NAD and PCK), marked by the two Saddle Variants, and malate formers (NADP), marked by the Variant 1 Bilobate (Figure 15).

Association between Morphotype and Rainfall

Association through the rate of recurrence between phytolith morphotypes and Rainfall-subcategories (Table 5) demonstrated that the Variant 1 Bilobate (22%, n = 176) and Polylobate (19%, n = 176) recurred mainly, but moderately in the in the >500mm S – subcategory. The Variant 2 Bilobate (49%, n = 176), recurred strongly in the in the >500mm S – subcategory, as well as in the <500mm S -subcategory (45%, n = 97) and >40% W –subcategory (49%, n = 125). Recurrence of the Variant 1 (35%, n = 97) and Variant 2 Saddle (23%, n = 97) was highest in the <500mm S – subcategory. The Trapezoid (32%, n = 125) and Reniform morphotypes (20%, n =

125) were most common in the >40% W –subcategory. Recurrence of the Variant 3 Bilobate, Cross, Rondel and Oblong morphotypes is generally low in all the subcategories (≤ 16% of species).

Relative abundance of GSSC-morphotypes calculated for the Rainfall-category (Table 6, Appendix 12) showed that the Variant 2 Bilobate was the predominant morphotype in all three of the subcategories (> 29% of total GSSC-morphotypes counted). Other morphotypes with high values were both Saddle Variants in the >500mm S – subcategory (27.7%, s.e. = 4.28 and 15.7%, s.e. = 3.37, n = 97), the Variant 1 Bilobate in the >500mm S – subcategory (16.6%, s.e. = 2.57, n = 176) and the Trapezoid morphotype in the >40% W –subcategory (17.4%, s.e. = 2.62, n = 125).

Altogether five morphotypes were shown not to be significantly different ($p < 0.05$) between subcategory pairs in the one-way ANOVA test for the rainfall category, namely the Variant 2 and 3 Bilobate, Polylobate, Cross as well as the Rondel morphotype (Table 17, Appendix 13). The >500S-subcategory was the most frequently differentiated by the Variant 1 Bilobate and the Variant 1 and 2 Saddle. The <500S-subcategory was most frequently differentiated by the Variant 2 Saddle and the >40%W-subcategory by the Trapezoid and Reniform morphotypes (Appendix 13). The fifth CA was carried out using only those morphotypes found to be significant in the ANOVA test for the Rainfall-subcategories. The first two dimensions of the CA explained a cumulative 100% of inertia, confirming the significance of the morphotypes with high-quality representation of row and column points (quality for all points = 1.0) (Figure 16 and Table 18, Eigenvalues). The Variant 1 Saddle

contributed the most relative inertia (0.337). This was confirmed by maximum row percentage values (Table 18, Percentages of row totals) which suggested a strong affiliation between the Variant 1 Saddle and <500S-subcategory (52.1%). Additional associations were between the Variant 1 Bilobate and >500S-subcategory (34.8%), the Variant 2 Saddle and <500S-subcategory (29.5%) and the Trapezoid morphotype and >40%W-subcategory (35.5%). In the two-dimensional matrix (Figure 16), the first dimension (contributing 77.52% of the total inertia) reflects a seasonal gradient, with cool, winter rainfall conditions represented by the Trapezoid, Oblong and Reniform morphotypes (negative values) and warm summer rainfall conditions represented by the Variant 1 and 2 Saddle morphotypes (positive values) The second dimension (contributing 22.48% of the total inertia) possibly reflects differences in precipitation patterns, with comparatively high rainfall conditions represented by the Variant 1 Bilobate (positive values) and low rainfall conditions represented by the two Saddle Variants (negative values).

Association between Morphotype and Habitat

Recurrence of GSSC-morphotypes amongst Habitat-subcategories (Table 5) revealed that the Variant 1 Bilobate was moderately frequent in the Desert grasses (19% of species, n = 26), Savanna grassland (22% of species, n = 157), Grassland biome (23% of species, n = 134), High altitude grassland (22% of species, n = 18) and Shady habitat –subcategories (25% of species, n = 43). The Variant 2 Bilobate recurred in 50% or more species in the Savanna grassland (n = 157), Fynbos grasses (n = 104), Forest grasses (n = 15), Damp soils (n = 82) and Swamps/Vleis – subcategories (n = 21). Representation of the Variant 3 Bilobate was modest in the

Forest grasses –subcategory (20% of species, n = 15) and comparatively low in the other subcategories (≤ 15%). Frequent occurrences of the Polylobate morphotype was recorded in the Grassland proper (22% of species, n = 134), Forest grasses (26% of species, n = 15), Swamps/Vleis (23% of species, n = 21) and Shady habitat –subcategory (39% of species, n = 43). The Variable 1 Saddle recurred most frequently in the Desert grasses (23% of species, n = 26), Nama-Karoo grasses (28% of species, n = 85), Savanna grassland (26% of species, n = 157), and Grassland biome –subcategory (20% of species, n = 134). Subcategories Desert grasses (34% of species, n = 26) and Succulent Karoo grasses (32% of species, n = 46), presented the highest recurrence of the Variant 2 Saddle, while the occurrence of the Trapezoid morphotype was most noticeable in the Fynbos grasses (32% of species, n = 104), Montane grassland (42% of species, n = 70) and High altitude grassland subcategory (55% of species, n = 18). The Oblong recurred most frequently in the Forest grasses (26% of species, n = 15) and Montane grassland –subcategories (24% of species, n = 70) and the Reniform morphotype in the Montane grassland (30% of species, n = 70) and High altitude grassland subcategories (50% of species, n = 18). The Cross morphotype recurred most often in the Swamps/vleis –subcategory (19% of species, n = 21), but was otherwise comparatively uncommon (< 15% of species).

Association between GSSC-morphotypes and Habitat-subcategories, based on the relative abundance of phytoliths (Table 6), indicated that the Variant 1 (18.9%, s.e. = 7.16, n = 26) and Variant 2 Saddle (24.3%, s.e. = 6.72, n = 26) were most common, while the Variant 3 Bilobate, Polylobate, Rondel and Reniform morphotypes were

rare in the Desert grasses –subcategory. There were no Cross and Oblong morphotypes recorded in the Desert grasses –subcategory. The Succulent Karoo – subcategory was best represented by the Variant 2 Bilobate (23.4%, s.e. = 5.12, n = 46) and Variant 2 Saddle (24.3%, s.e. = 5.72, n = 46) morphotypes. The Variant 2 Bilobate and Variant 1 Saddle respectively provided the highest values in the Nama-Karoo grasses -subcategory (30.3%, s.e. = 4.26 and 22.6%, s.e. = 4.31, n = 85), Savanna grassland -subcategory (36.5%, s.e. = 3.41 and 23.9%, s.e. = 3.28, n = 157) and the Grassland biome subcategory (35.4%, s.e. = 3.59 and 18.0%, s.e. = 3.18, n = 134). The Variant 2 Bilobate was also the most prominent morphotype in the Forest grasses –subcategory (36.7%, s.e. = 10.77, n = 15), whereas the Variant 2 Saddle and Reniform morphotype were absent. The Variant 2 Bilobate and Trapezoid morphotype respectively accounted for the highest values in the Fynbos grasses – subcategory (35.9%, s.e. = 3.92 and 16.8%, s.e. = 2.76 n = 104), and the Montane grassland –subcategory (24.3%, s.e. = 4.36 and 24.6%, s.e. = 3.92, n = 70). The Variant 2 Bilobate respectively accounted for more then 30% of the total number of GSSC-phytoliths counted in the Damp soils (36.4%, s.e. = 4.55, n = 82), Swamps/Vleis (40.2%, s.e. = 9.31, n = 21) and Shady habitat –subcategories (31.1%, s.e. = 5.65, n = 43). Maximum values in the High altitude grassland –subcategory were provided by the Variant 1 Bilobate (21.8%, s.e. = 9.91, n = 18) and Trapezoid morphotypes (25.5%, s.e. = 7.04, n = 18).

The one-way ANOVA indicated that the Variant 3 Bilobate (p = 0.4110) and Cross morphotype (p = 0.1951) was not significantly different between the habitat subcategories included in the study (Table 19). Tukey's HSD tests further

demonstrated that the Variant 1 and 2 Bilobate, Polylobate, Rondel and Oblong morphotypes were significantly different between a third or less, subcategory pairs (Appendix 15) and were left out of the subsequent CA. The Variant 1 Saddle and Trapezoid most often significantly distinguish between the Savanna and Montane grassland subcategories, and the Variant 2 Saddle, between the Succulent Karoo and Desert subcategories. The Reniform morphotype most often significantly differentiate between the High altitude and Montane grassland subcategories.

The sixth CA, carried out using only those morphotypes found to be significant in the ANOVA, resulted in two dimensions that explain a cumulative 94.64%% of inertia (Figure 17 and 18), with a maximum of three dimensions extracted (Table 20, Eigenvalues). The Variant 1 Saddle delivered the highest contribution to total relative inertia (0.400) (Table 20, Column coordinates), which is also reflected in the row percentage values (Table 20, Percentages of row totals). The row frequencies showed close association between the Variant 1 Saddle and the Savanna grassland- (77.4%) and Grassland biome –subcategories (74.6%). High affiliation values were also indicated between the Trapezoid morphotype and the Montane grassland- (64.6%) and High altitude grassland –subcategories (63.1%); and the Variant 2 Saddle and the Desert grasses- (39.0%) and Succulent Karoo grasses –subcategory (48.4%). In the two-dimensional representation, the first dimension accounts for 75.81% of the total inertia and is driv en by a climatic gradient between C_4 grassland and savanna habitats, represented by the Variant 1 Saddle and primarily cool or wet C_3 grassland habitats, represented by the Trapezoid morphotype (Fig 17 and 18). The second dimension accounts for 18.83% of the total inertia and may represent a

surface temperature gradient that is evidently reflected in the percentage row values of the Variant 2 Saddle's association with the Succulent Karoo grasses- (48.4%) and Forest grasses –subcategory (0.00%).

Table 7. Spearman's rank-order correlation between association through the rate of recurrence of GSSC-morphotypes (Table 3) and relative abundance of GSSC-morphotypes (Table 4) in the sample (309 species).

Table 9. Dimension contributions to inertia in CA for GSSC-morphotypes.The eigenvalues are the squared singular values that add up to the Total Inertia which is listed in the header of the Eigenvalue spreadsheet below. Mass represents the row and column totals of the matrix of relative frequencies. Quality reflects the quality of representation of each respective data point in the coordinate system as defined by the respective numbers of dimensions. A low Quality means that the current number of dimensions does not well represent the respective row or column.

Table 11. Dimension contributions to inertia in CA using only morphotypes found to significantly differentiate between six subfamilies. The eigenvalues are the squared singular values that add up to the Total Inertia which is listed in the header of the Eigenvalue spreadsheet below. Mass represents the row and column totals of the matrix of relative frequencies. Quality reflects the quality of representation of each respective data point in the coordinate system as defined by the respective numbers of dimensions. A low Quality means that the current number of dimensions does not well represent the respective row or column. The row frequencies (percentage of row totals) are standardized, so that their sum in each row is equal to 100%. High row frequencies are marked.

Table 18. Dimension contributions to inertia in CA using only morphotypes found to significantly differentiate between Rainfall subcategories. The eigenvalues are the squared singular values that add up to the Total Inertia which is listed in the header of the Eigenvalue spreadsheet below. Mass represents the row and column totals of the matrix of relative frequencies. Quality reflects the quality of representation of each respective data point in the coordinate system as defined by the respective numbers of dimensions. A low Quality means that the current number of dimensions does not well represent the respective row or column. The row frequencies (percentage of row totals) are standardized, so that their sum in each row is equal to 100%. High row frequencies are marked.

Discussion and Conclusion

Production and affiliation between GSSC- phytoliths

Rates of morphotype production appear to be variable. Relative abundance values indicate that the 1st and 2nd Bilobate Variant, Variant 1 Saddle as well as the Oblong morphotype, are produced in comparably higher quantities, while the Variant 3 Bilobate, Polylobate and Cross, are produced in lower amounts by the species that produce them (Figure 10). However, the potential for bias as a result of variable production of GSSC-phytoliths in species is mitigated by the fact that positive covariation is demonstrated between *relative abundance* and the *rate of recurrence* of the GSSC-morphotypes. Strong morphological affilation has been expressed by clustering of the Lobate, Saddle and Trapeziform morphotype classes in the first correspondence analysis (Figure 11), alluding to genetic control, which also suggests that association between GSSC-phytoliths is not completely random, as implied by the complexities of multiplicity and redundancy (Rovner 1983).

The effects of multiplicity and redundancy are more noticeable at subfamily-level, because the hierarchal position of subfamily, as a taxonomic unit in biological classification, is based on inherent, homologous characters other than phytolith morphology. The original classification scheme by Twiss *et al.* (1969) has shown that several GSSC-phytolith morphotypes associate well with particular North American subfamilies, and mainly according to photosynthetic pathway. This trend is corroborated by the study, which also indicates that as a result of multiplicity and redundancy, comparatively few morphotypes appear to be really meaningful indicators at subfamily level (Appendix 8), namely the Variant 1 Saddle

(Chloridoideae), Variant 2 Saddle (Aristidoideae), Variant 2 Bilobate (Panicoideae), the Trapezoid morphotype (Ehrhartoideae and Danthionoideae) and the Oblong morphotype (Pooideae).

GSSC-phytoliths and the environment

Inter-relationships based on GSSC-morphotype assemblages amongst the habitat-, rainfall- and photosynthetic pathway - categories, are illustrated in Figure 19. Dimension contributions to total inertia and the degree of separation shown by the two-dimensional plots in the six sets of CA, suggest that the GSSC-morphotypes selected to describe the different subcategories are ecologically appropriate, (cumulative percent inertia > 90% and number of dimensions extracted ≤ 3, Table 21). It is evident that short cell phytolith association in grasses is primarily driven by a temperature gradient, marked by cool growing temperatures (as pointed out by the C_3 photosynthetic pathway -category, versus warm growing temperatures (i.e. C_4 photosynthetic pathway) (Figure 19, Dimension 1). Rainfall seasonality and relative moisture, to a lesser extent, also contribute to the general pattern (Figure 19, Dimension 2). This observation is by and large supported by significant positive correlation between C_4 -species abundance and the <500mm summer rainfall niche ($r^2 = 0.6521$; $r = 0.8075$, $p = 0.0008$), and significant negative correlation between C_3-species abundance and <500mm summer rainfall niche ($r^2 = 0.6427$; $r = -0.8017$, $p = 0.0010$) (Figure 20). One possible example of the influence of relative moisture is exemplified in the Chloridoideae where the marsh grass species, *Sporobolus ludwiggi* show Bilobate morphology, while *Sporobolus panicoides*, which do not occur in wet environments, essentially exhibit saddle-shaped GSSC-morphotypes

(Appendix 2).

The Variant 2 Bilobate, Variant 1 Saddle, Variant 2 Saddle, Trapezoid and Reniform morphotypes affiliate with several subcategories, as opposed to the Variant 3 Bilobate, Polylobate, Cross and Rondel morphotypes (Table 22). The Variant 1 Bilobate appears to be a suitable indicator of mesic and warm-season, growing conditions, while the Variant 2 Bilobate seems to indicate towards a gradient between C_4 aspartate formers and C_3 grasses. The Variant 3 Bilobate bears no significance to any of the subcategories whereas the Cross and Rondel morphotypes contributes only on subfamily level with their association to the Panicoideae and Pooideae, respectively. The Variant 1 Saddle is a meaningful predictor of the Chloridoideae subfamily, warm and locally mesic to regionally dry summer rainfall conditions and environments related to Nama-Karoo and Savanna grass communities as well as the Grassland Biome. The Variant 2 Saddle is well-associated with the Aristidoideae subfamily, dry to arid summer rainfall conditions, as well as conditions related to Desert and Succulent-Karoo grass communities. The Trapezoid and Reniform morphotypes strongly associates with the Pooideae subfamily, C_3, winter rainfall conditions, and environments relating to relatively moist, edaphic grasslands, forest habitats and montane grasslands. The Oblong morphotype is an appropriate indicator of the Pooideae subfamily and C3, winter rainfall conditions in general.

Applicability to fossil phytolith assemblages

It was demonstrated that grass short-cell phytoliths consistently follows meaningful environmental traits that are rooted in the relationship between phytolith shape and the ecological niche of grasses. The thesis examined the predictive power of GSSC-

phytoliths within a quantitative model that successfully assigned ecological meaning to them, irrespective of taxonomic affiliation.

The model allowed for comparison of geographically diverse grass phytolith assemblages from indigenous and endemic species, by converting them into one homogenous group represented by ecological categories. Consequently, this also applies to temporally diverse fossil assemblages, making it a potentially useful method for acquiring palaeoenvironmental data through GSSC-phytolith analysis. This implies the use of interpretive techniques to work backwards in time from the known present to the unknown past. To make extrapolations about the past, we must assume that the principles underlying the structure of natural systems in the past were the same as those of the present. Thus, inferences can be made about the palaeontological record with the knowledge of present processes (Sampson 1970).

It is recognized that the effects of post-depositional processes on the preservation of fossil phytolith assemblages, are potential obstacles to refining scale in terms of localized conditions or longer term regional changes (Fredlund and Tieszen 1994). The ecological significance of modern GSSC-morphotypes provides a means to reconstruct palaeoenvironmental scenarios from fossil phytolith assemblages, albeit on a relatively wider scale, but using modern soil assemblages as a point of reference may also pose a problem. Environmental signals provided by modern soil assemblages affected by widespread human impacts on vegetation, may be skewed by underrepresentation (vegetation degradation, afforestation) or misrepresentation (deforestation, crop cereals). For example, overgrazing by domestic animals is seen as the main cause for vegetation degradation in the South African region, while

replacement of mostly fynbos and grassland by alien timber species comprises a combined area of over fourteen thousand square kilometers (Hoffman 1997) In addition, crop cultivation, including several kinds of cereals, make up close to fifteen percent of total potential arable land in South Africa (Hoffman 1997). In the end, interpretation of the scale represented by fossil phytolith assemblages is contingent on understanding the context of a fossil locality. In light of this, the model was briefly assessed against several palaeoenvironmental interpretations provided by three fossil faunal assemblages (Appendix 16).

Conclusion

Knowledge about the ecological significance of modern GSSC-morphotypes and other morphologically diagnostic phytolith morphotypes remain critically under-researched. The investigations carried out in this study have increased our understanding of the ecological paprameters in which GSSC-morphotypes operate. The central hypothesis, namely that the morphology of South African grass short-cell phytoliths consistently follows meaningful environmental traits that are rooted in the relationship between phytolith shape and the ecological niche of grasses, have been validated. Several meaningful ecological trends were demonstrated by the GSSC-morphotypes in this study, which underscores the advantage of investigating phytolith systematics with the aid of adequate comparative reference collections. Standardization of grass phytolith assemblages using short cell sums have yielded a proxy for regional environmental conditions. The challenge for future research will be to refine the methodology further by testing it through wide-ranging actualistic studies.

Table 21. Number of dimensions that explain 100% of the variability and the sum total of inertia for the first two dimensions that were extracted from each of the six sets of CA carried out in the study.

Category	No. of Dimensions Extracted	Cumulative % Inertia of Dim 1 and 2
Morphotype	10	48.9%
Subfamily	5	71.7%
Photosynthetic pathway (C3 and C4 subtypes)	3	96.9%
Photosynthetic pathway (C4 subtypes)	2	100.0%
Rainfall	2	100.0%
Habitat	3	94.6%

APPENDICES

Appendix 1: Atlas of GSSC-phytoliths extracted from grass leaves.

Appendix 2: Atlas of 227 grass leaf epidermis slide vouchers.

Appendix 3: Indicator matrix of GSSC-morphotypes recorded in 309 grass species.

Appendix 4: Spearman's rank-order correlation between association through rate of recurrence of morphotypes and relative abundance of morphotypes.

Appendix 5: Basic statistics of the number of GSSC-morphotypes counted for each GSSC-morphotype subcategory.

Appendix 6: GSSC-phytolith abundance as a proportion of all morphotypes per category.

Appendix 7: Basic statistics of the number of GSSC-morphotypes counted for each subfamily subcategory.

Appendix 8: Subfamily: Tukey's HSD test for unequal sample sizes.

Appendix 9: Basic statistics of the number of GSSC-morphotypes counted for each photosynthetic pathway subcategory, including C_4 subtypes.

Appendix 10: Tukey's HSD test for unequal sample sizes in the Photosynthetic pathway-category (including C_3 and C_4).

Appendix 11: Tukey's HSD test for unequal sample sizes in the photosynthetic pathway - category (C_4 only).

Appendix 12: Basic statistics of the number of GSSC-morphotypes counted for each Rainfall subcategory.

Appendix 13: Tukey's HSD test for unequal sample sizes in the Rainfall-category

Appendix 14: Basic statistics of the number of GSSC-morphotypes counted for each habitat subcategory.

Appendix 15: Tukey's HSD test for unequal sample sizes in the Habitat-category.

Appendix 16: Comparison of GSSC-phytoliths against three Palaeoenvironmental Scenarios.

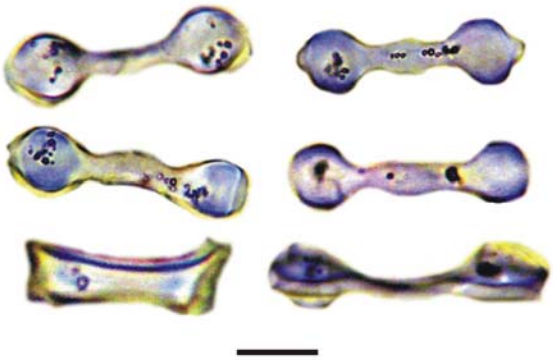
Appendix 1: Atlas of GSSC-phytoliths extracted from grass leaves.

Five-centimeter leaf sections were removed from voucher specimens of mature individuals housed at the herbarium of the Department of Botany at the National Museum in Bloemfontein, the National Herbarium of Pretoria and the Bolus Herbarium at the University of Cape Town. Standard dry-ashing procedures were followed to extract phytoliths from the five-centimeter leaf sections (Piperno 1988; Parr *et al.* 2001). Parr *et al*. (2001) has demonstrated that the dry ashing technique produces less residual plant matter than the wet-ashing technique with no detectible evidence of morphological impact caused by the former method. The leaf sections were rinsed with distilled water, transferred to crucibles and burnt in a furnace at 500°C for 6 h. The burnt residue was treated with 10%HCl and centrifuged (@ 2500 rpm for 5 minutes), re-suspended in distilled water and centrifuged again. The supernatant was discarded and the silica residue placed on microslides, mounted in silicon oil for rotation and finally in a rigid medium (DPX Mountant) for permanent storage. Photographs were taken at X400 and X1000 magnification with a digital camera mounted on a 50i Nikon polarizing light microscope. GSSC-phytoliths are presented as composites of several photomicrographs. Scale bar = 10 micron.

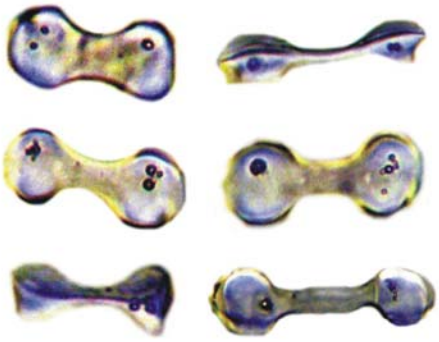
List of subfamilies and genera illustrated in Appendix 1.

Subfamily	Tribe
Aristidoideae	Aristideae
Arundinoideae	Arundineae
Bambusoideae	Bambuseae
Chloridoideae	Cynodonteae Eragrostideae Pappophoreae
Danthionioideae	Danthonieae
Ehrhartoideae	Ehrharteae Oryzeae
Panicoideae	Andropogoneae Arundinelleae Paniceae
Pooideae	Aveneae Brachypodieae Bromeae Meliceae Poeae Stipeae Triticeae

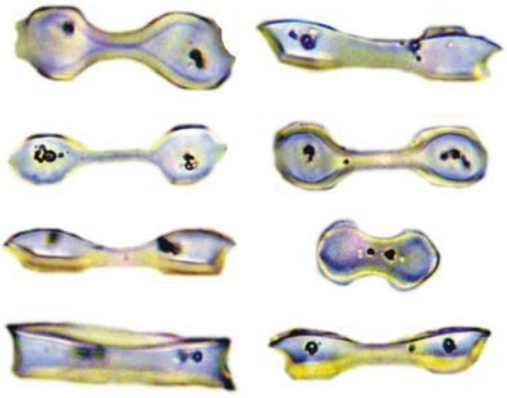
Aristidoideae
Tribe: Aristideae



Aristida adscensionis

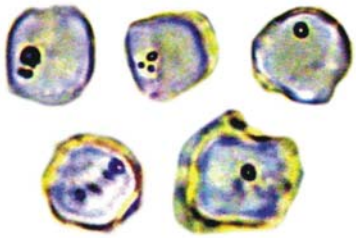


Aristida congesta

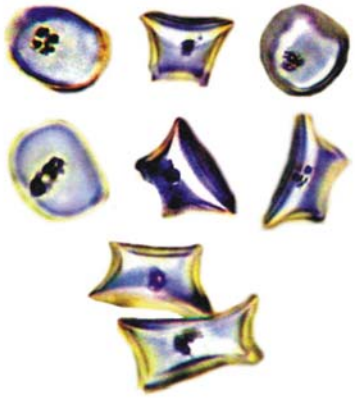


Aristida diffusa

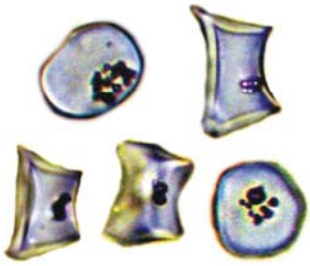
Aristida junciformis



Stipagrostis obtusa

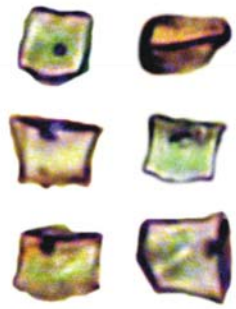


Stipagrostis namaquensis

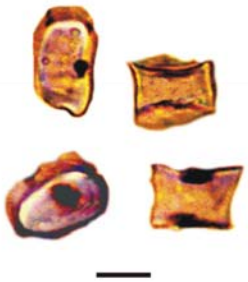


Stipagrostis uniplumis

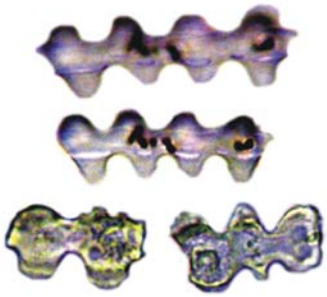
Arundinoideae
Tribe: Arundineae



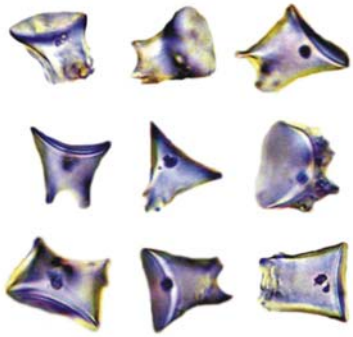
Dregechloa calviniensis



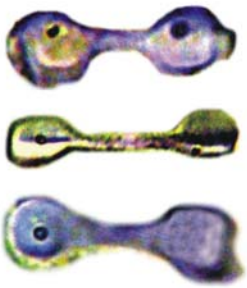
Dregechloa pumila



Elytrophorus globularis

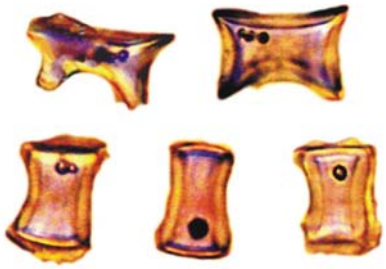


Phragmites australis

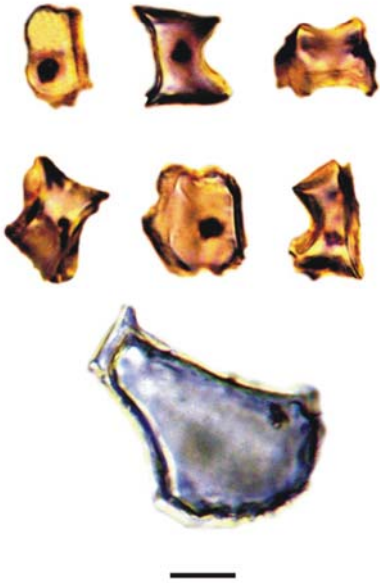


Styppeiochloa gynoglossa

Bambusoideae
Tribe: Bambuseae



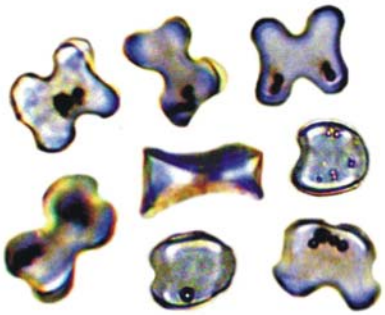
Bambusa vulgaris



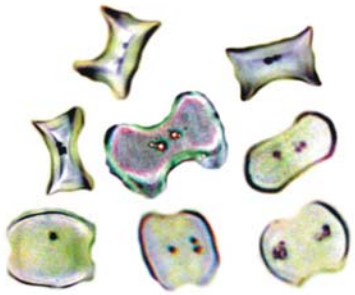
Thamnocalamus tessellatus

Olyra latifolia

Chloridoideae
Tribe: Cynodonteae

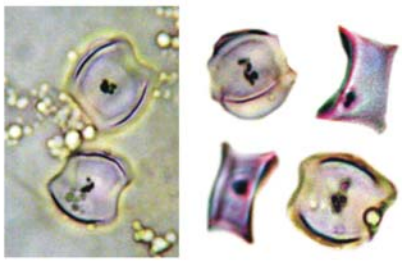


Catalepis gracilis

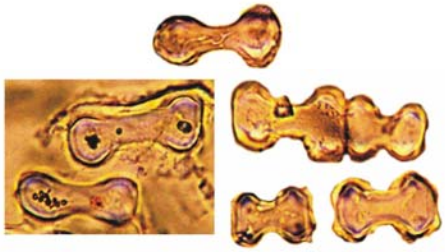


Chloris gayana

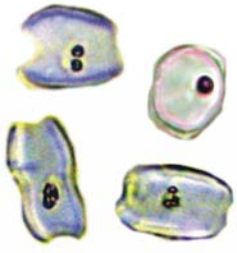
Chloris pycnothrix



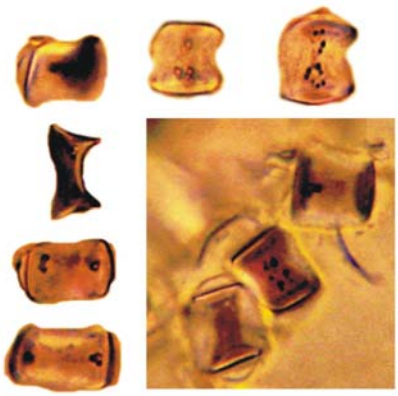
Chloris virgata



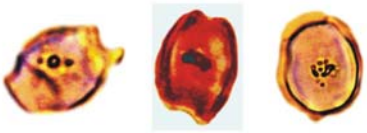
Ctenium concinnum



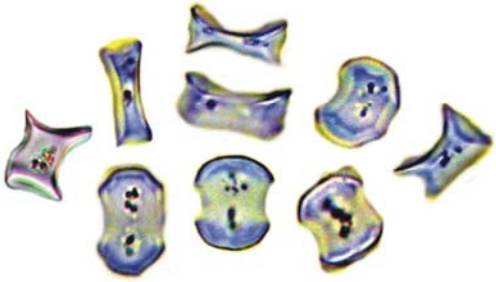
Cynodon dactylon



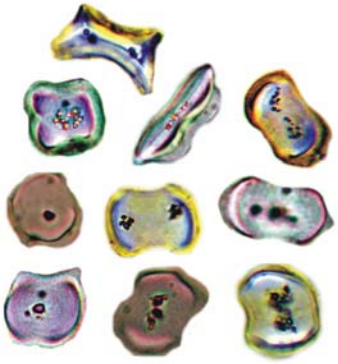
Enteropogon machrostachys



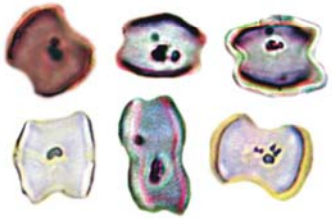
Eustachys mutica



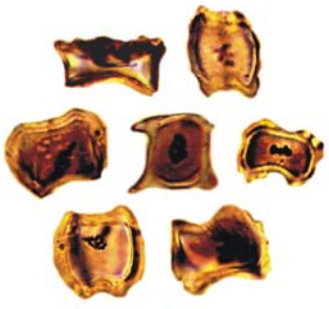
Eustachys paspaloides



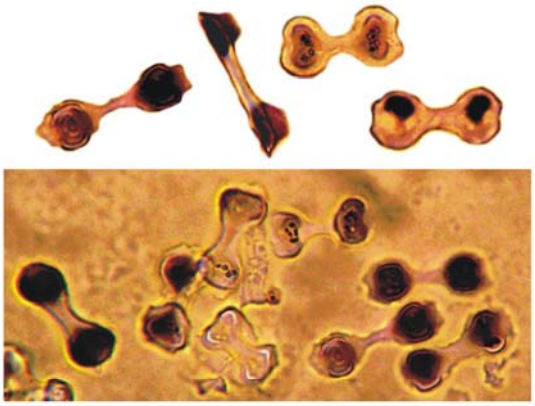
Harpochloa falx



Michrochloa caffra

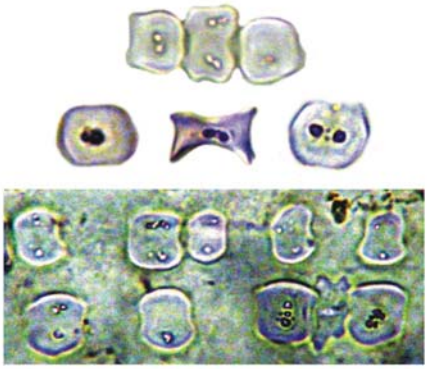


Michrochloa kunthii

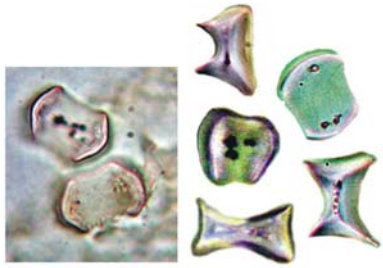


Perotis indica

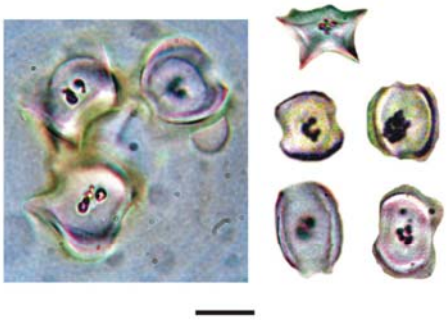
Perotis patens



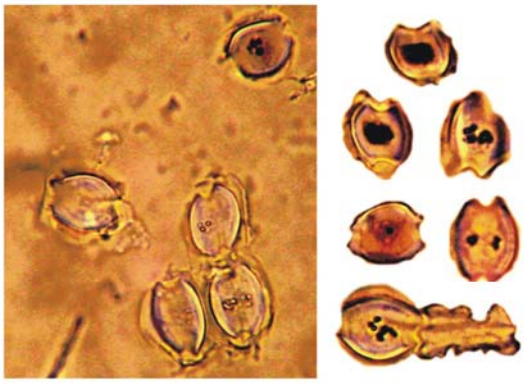
Polevansia rigida



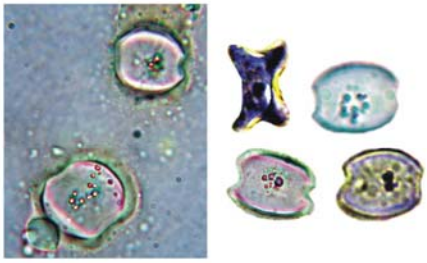
Rendlia altera



Tragus berteronianus

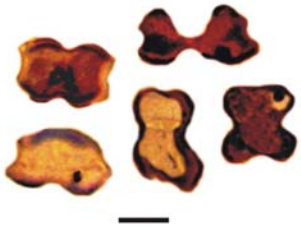


Tragus koeleroides

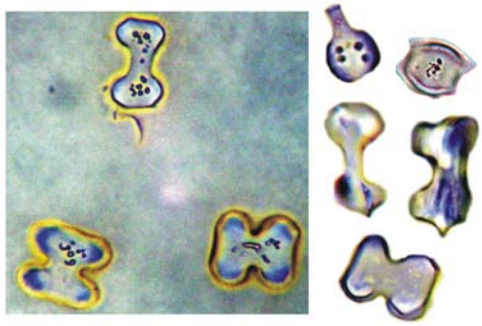


Tragus racemosus

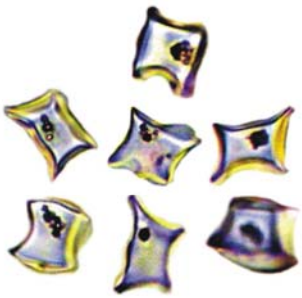
Chloridoideae
Tribe: Eragrostideae



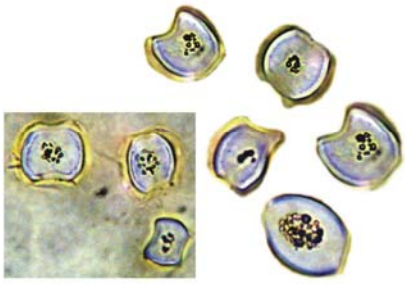
Acrachne racemosa



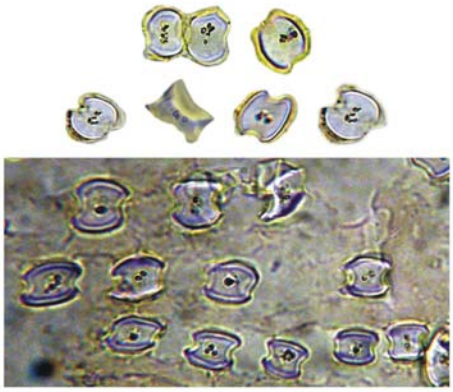
Bewsia biflora



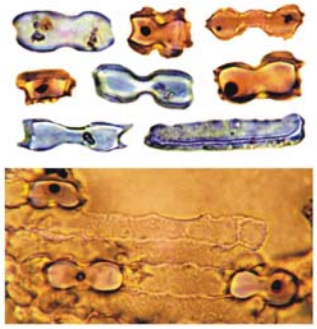
Cladoraphis spinosa



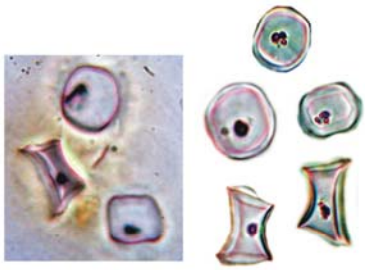
Coelachyrum yemenicum



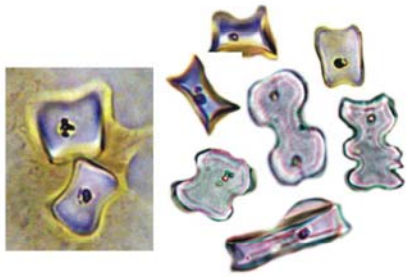
Dactyloctenium australe



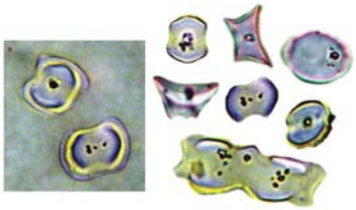
Diandrochloa namaquensis



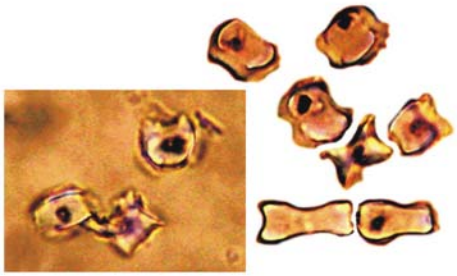
Dinebra retroflexa



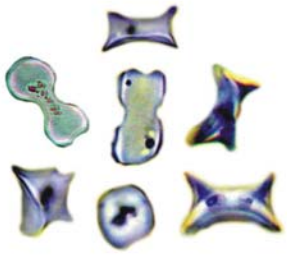
Diplachne fusca



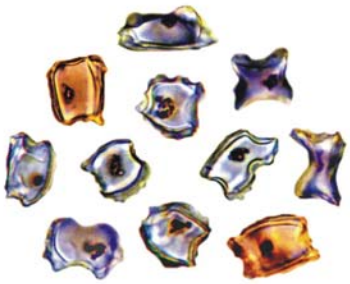
Eleusine coracana



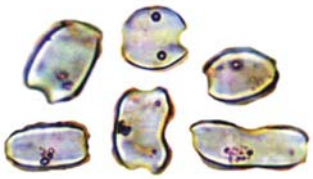
Eragrostis bicolor



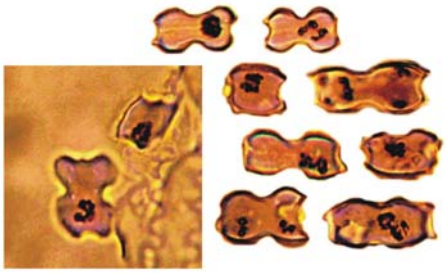
Eragrostis capensis



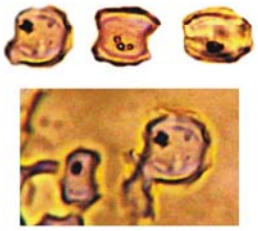
Eragrostis chloromelas



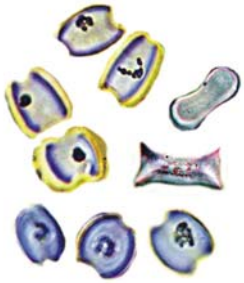
Eragrostis denudata



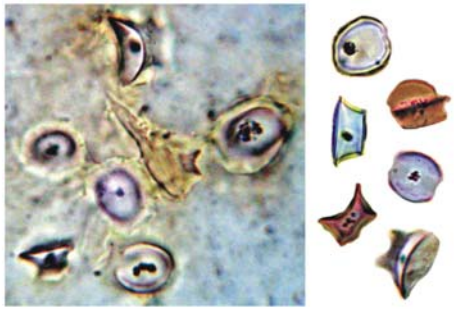
Eragrostis macrochlamys (138)



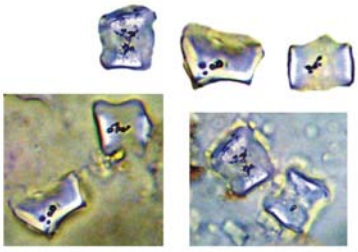
Eragrostis micrantha



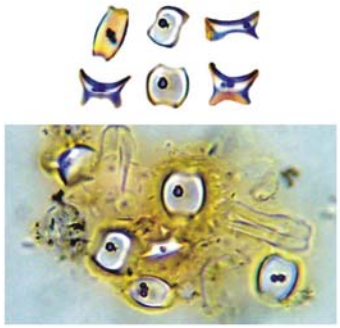
Eragrostis obtusa



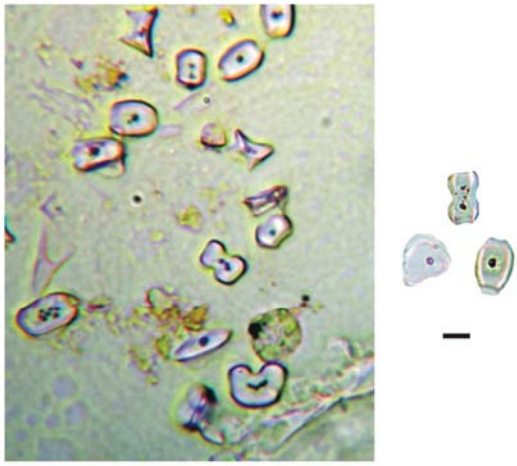
Fingerhuthia africana



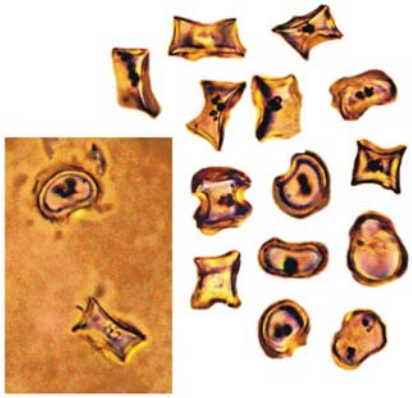
Oropetium capense



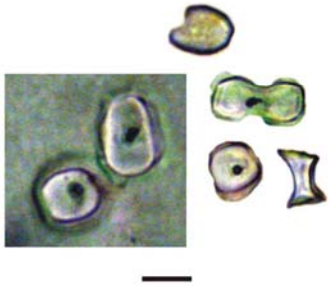
Pogonarthria squarrosa



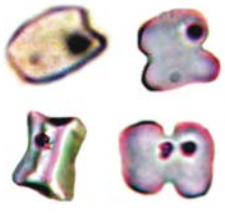
Sporobolus africanus



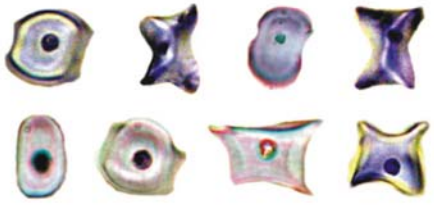
Sporobolus filifolius



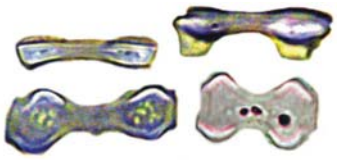
Sporobolus fimbriatus



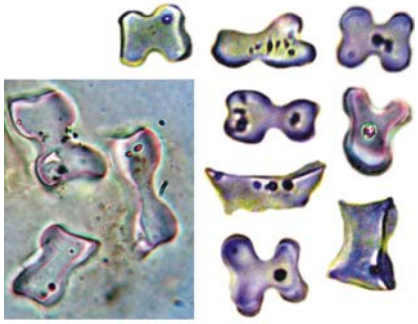
Stiburus alopecuroides



Tetrachne dregei

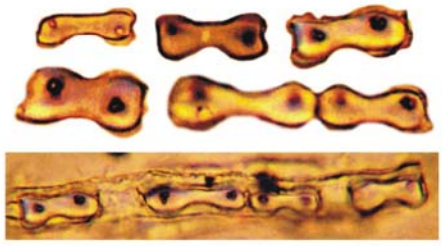


Trichoneura grandiglumis



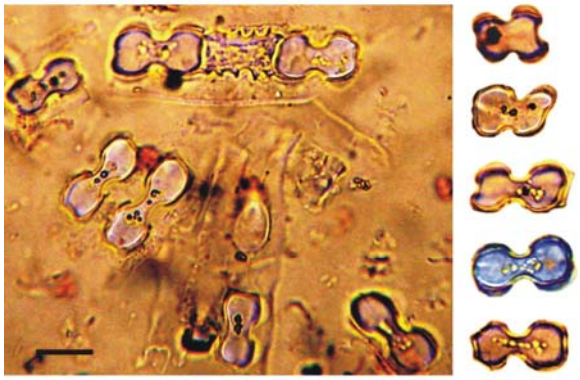
Triraphis andropogonoides

Chloridoideae
Tribe: Pappophoreae

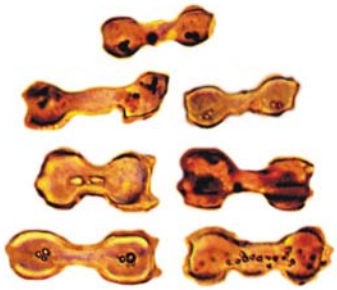


Enneapogon desvauxi

Enneapogon scaber



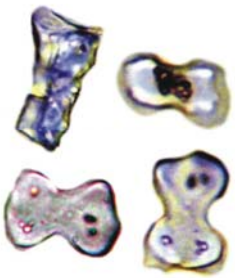
Schmidtia bulbosa



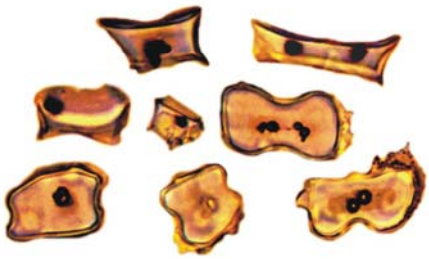
Schmidtia kalahariensis

Schmidtia pappophoroides

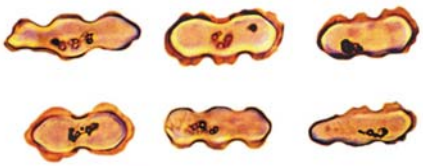
Danthionioideae

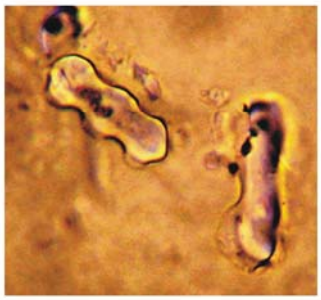


Centropodia glauca

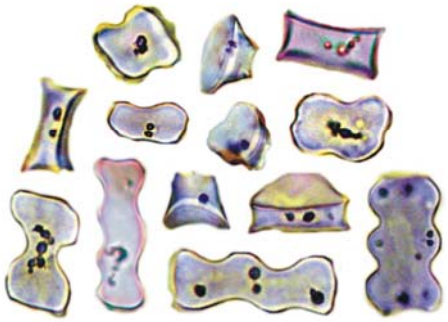


Chaetobromus dregeanus

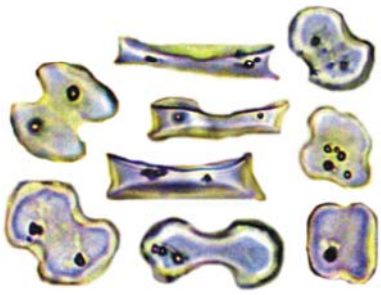




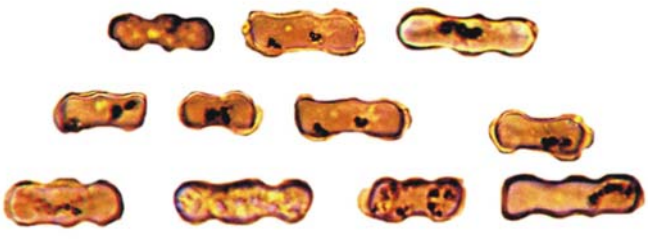
Chaetobromus involucratus



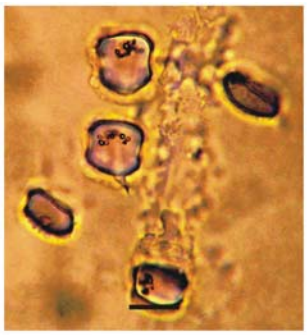
Karroochloa curva

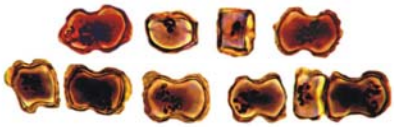


Karoochloa purpurea



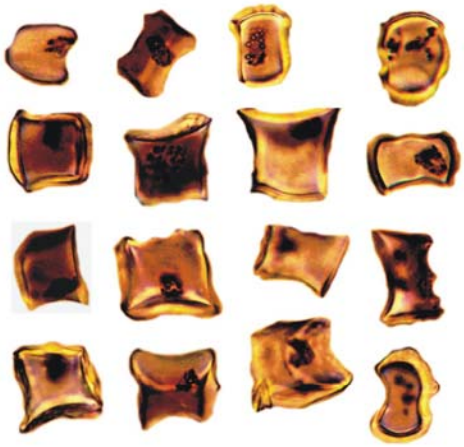
Karroochloa schismoides



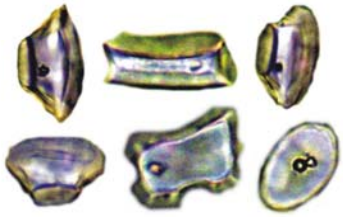


Karroochloa tenella

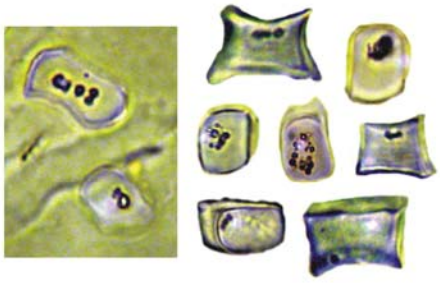
Merxmuellera lupulina



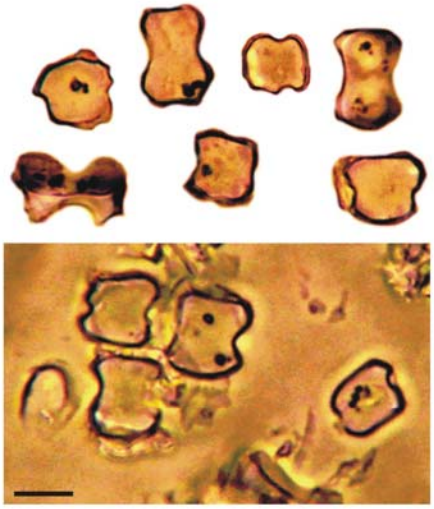
Merxmuellera rufa



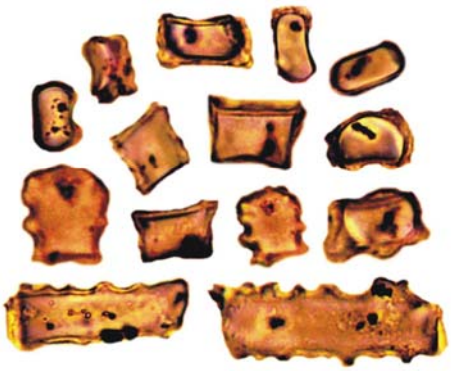
Merxmuellera stricta



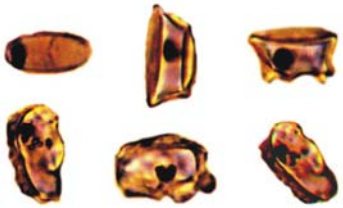
Pentaschistis ancifolia



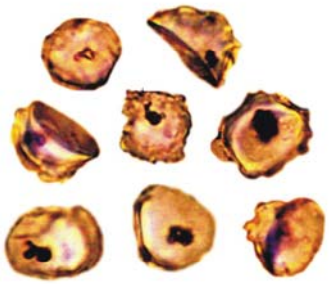
Pentaschistis colerata



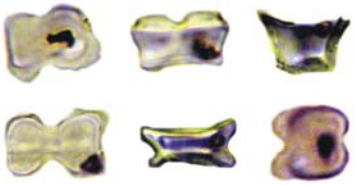
Pentaschistis curvifolia

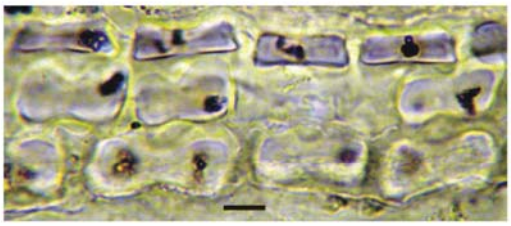


Pentameris longiglumis

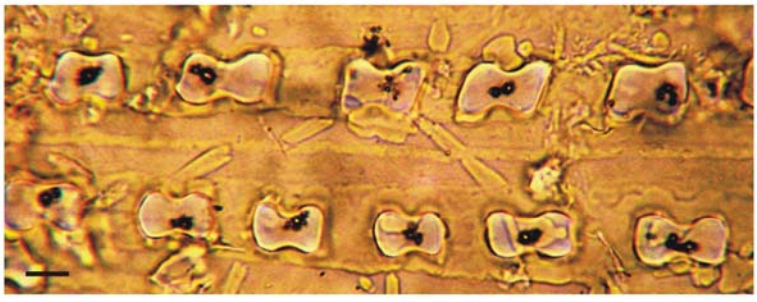


Pentameris macrocalycina

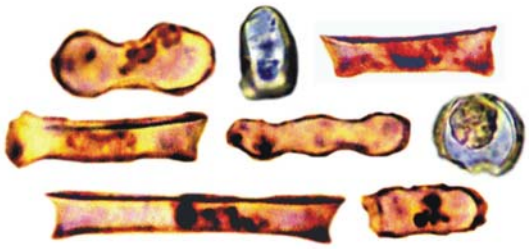




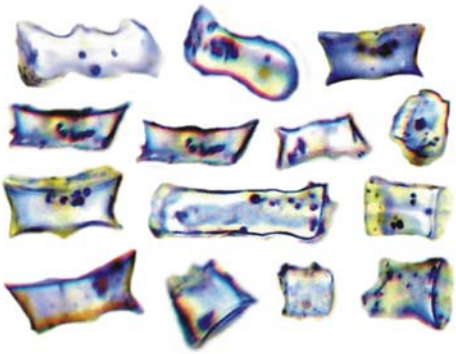
Pseudopentameris brachyphylla



Pseudopentameris macrantha

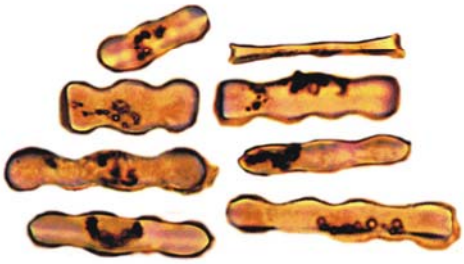


Schismus barbatus



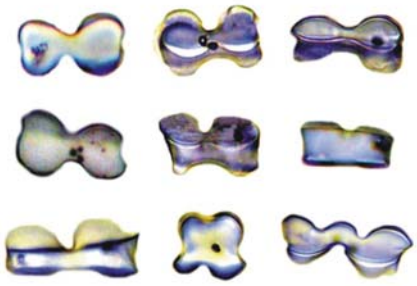
Schismis inermus

Tribolium uniolae



Urochlaena pussilla

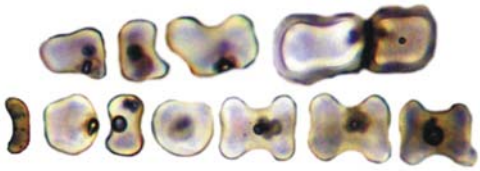
Ehrhartoideae
Tribe: Ehrharteae



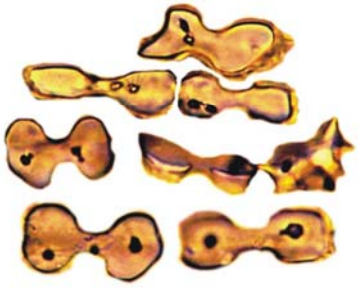
Ehrharta bulbosa

Ehrharta calycina

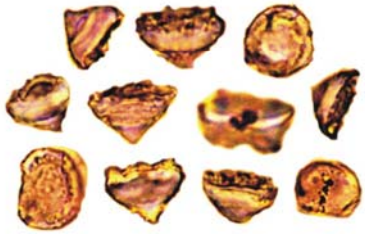
Ehrharta delicutula



Ehrharta longiflora

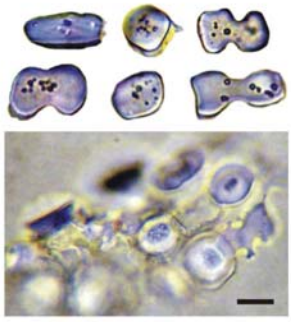


Ehrharta microlaena



Ehrharta ramosa

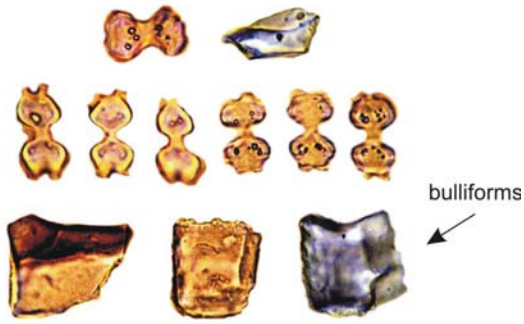
Ehrharta rehmanni



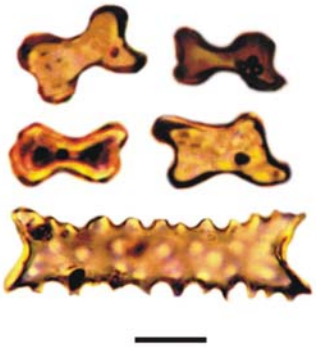
Ehrharta thunbergi

Ehrhartoideae
Tribe: Oryzeae

Leersia hexandra



Oryza longistaminata



Prosphytochloa prehensilis

Panicoideae

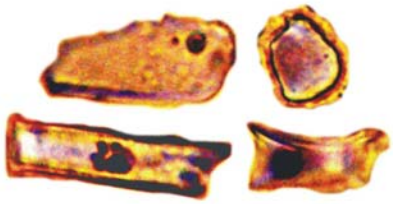
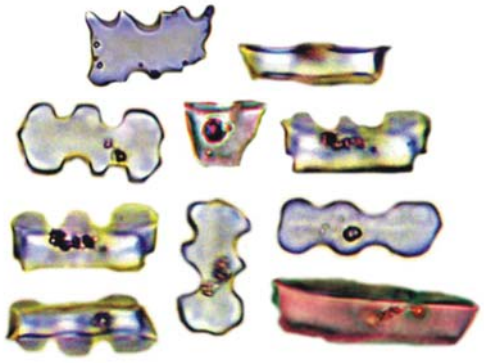
Bromus commutatus



Bromus pectinatus

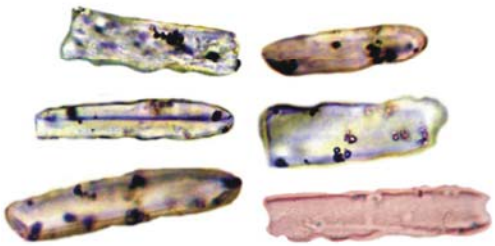
Bromus rigidus

Pooideae
Tribe: Meliceae

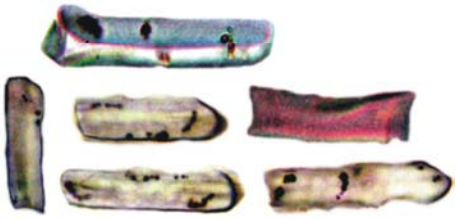


Melica racemosa

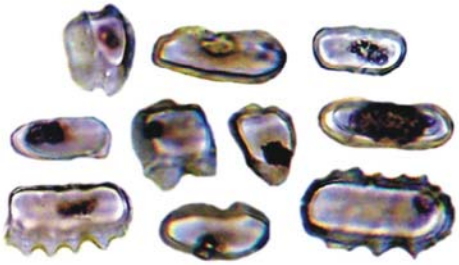
Pooideae
Tribe: Poeae



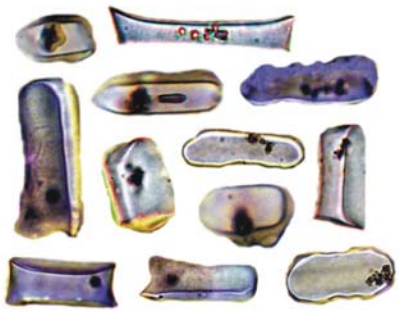
Briza maxima



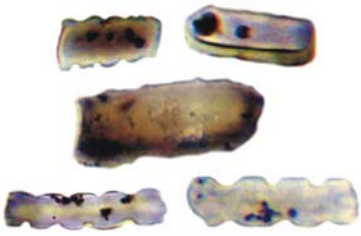
Briza minor



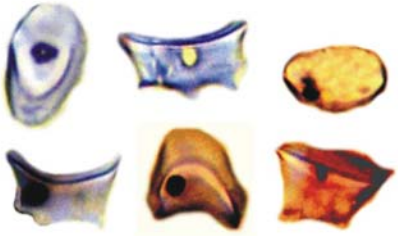
Festuca eliator



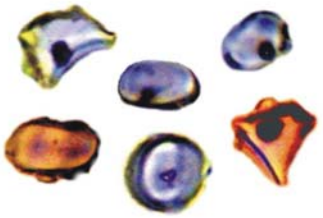
Festuca scabra



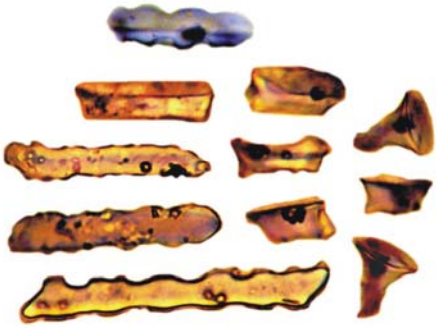
Poa annua



Puccinellia acroxantha

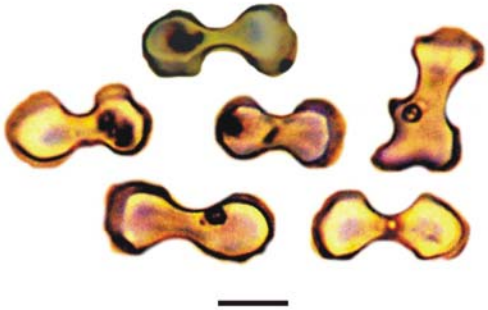


Puccinellia fasciculata

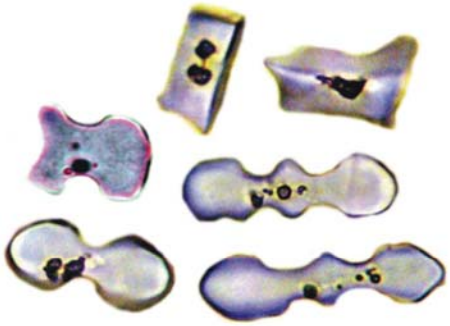


Vulpia bromoides

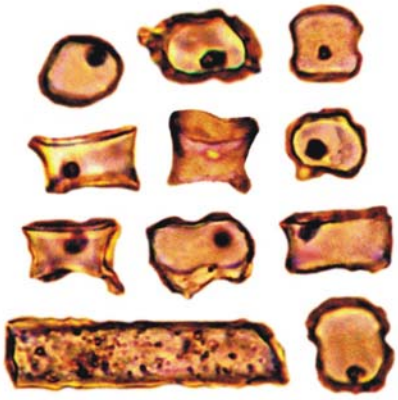
Pooideae
Tribe: Stipeae



Stipa capensis

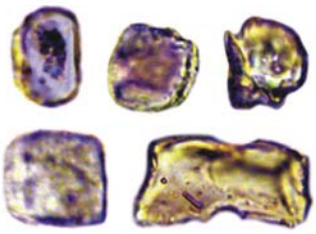


Stipa dregeana

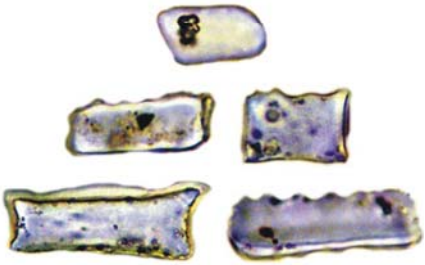


Stipa papposa

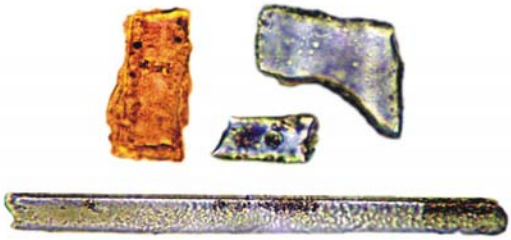
Pooideae
Tribe: Triticeae



Secale africanum



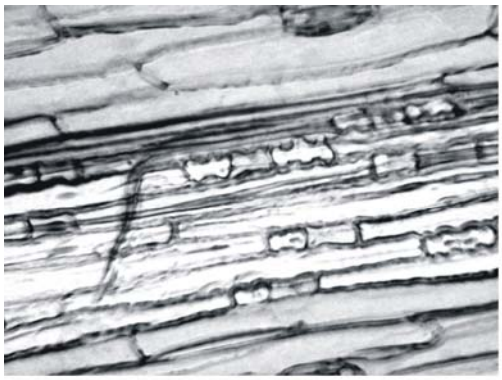
Hordeum capense



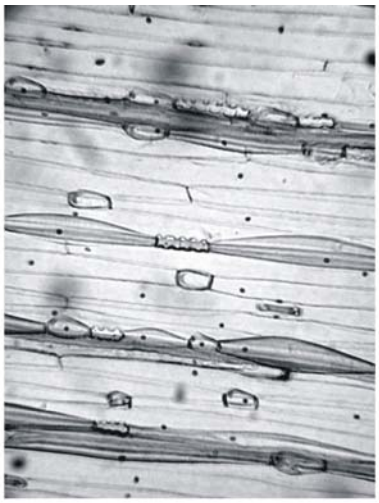
Thinopyrum distichum

Appendix 2: Atlas of 227 grass leaf epidermis slide vouchers.

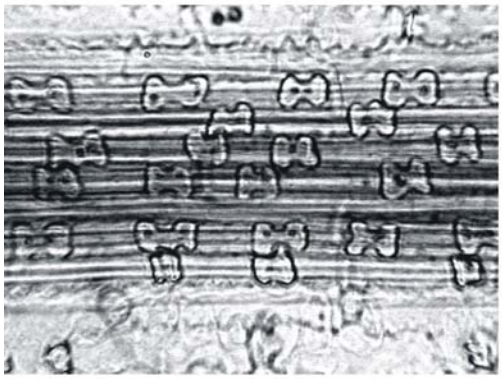
The collection consists of prepared slide vouchers of fully articulated grass leaf epidermis sections from the Roger Ellis collection housed at the National Herbarium of Pretoria. Photographs were taken with a digital camera mounted on a polarizing light microscope (x160 and x400 magnification). The photomicrographs are listed in alphabetical order with the species name, followed by the name of the collector, collection number, reference number in parenthesis and details regarding habitat-requirements of each species.



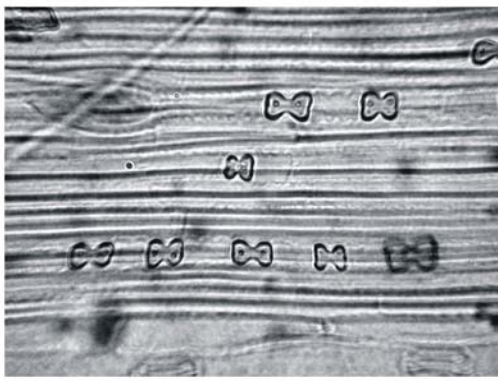
Agrostis barbuligera Ellis 5710 (7786)
Mountain grassland



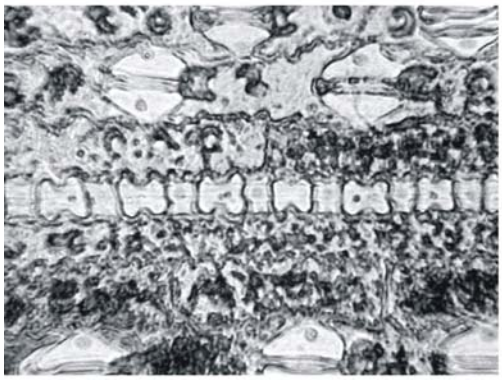
Agrostis bergiana Ellis 5698 (7788)
Mountain grassland, wet places



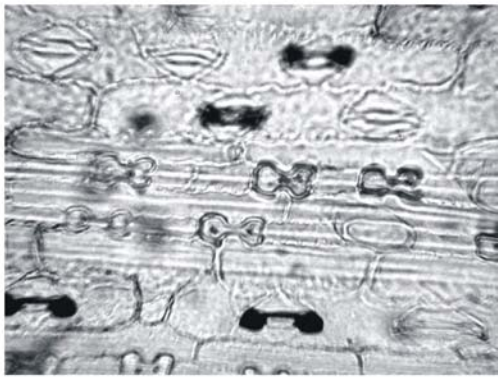
Alloteropsis semialata Saayman
24 (8191) Grassland, bushveld



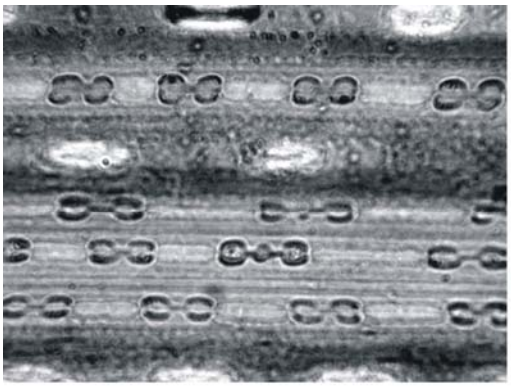
Andropogon appendiculatus Ellis 94
(8195) Wet, shady places



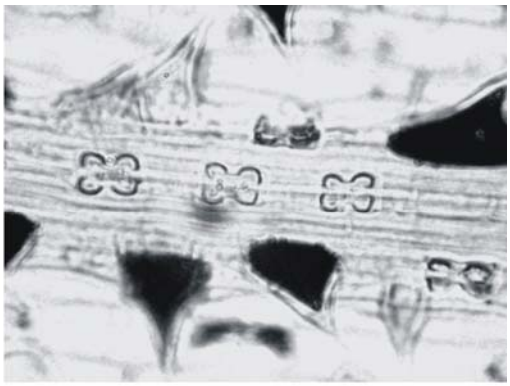
Andropogon gayanus Ellis 3690
(8197) Bushveld



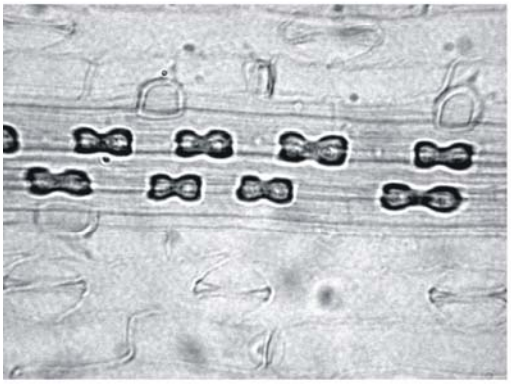
Andropogon huillensis De Wet 967
(8200) Wet places, sand



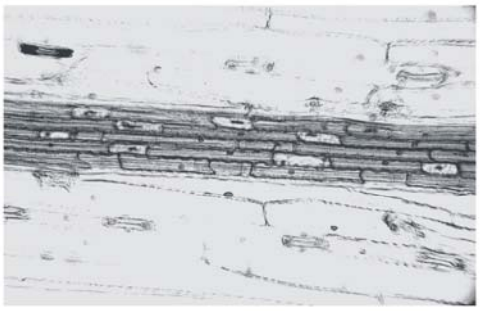
Andropogon laconosus Ellis 2814
(8201) Swampy places, high alt.



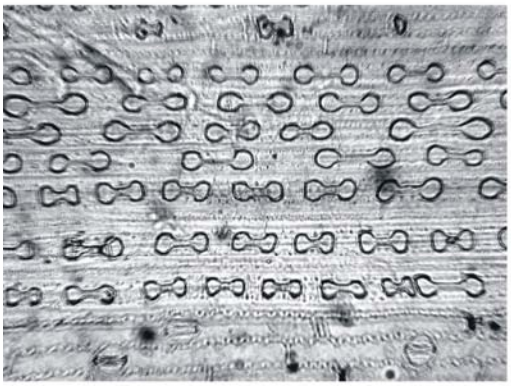
Anthephora argentea Ellis 877
(8207) Sandy soil, Kalahari.



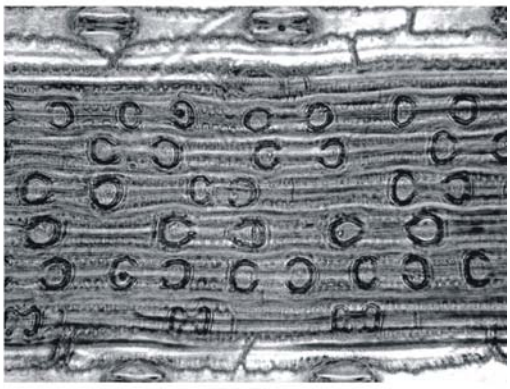
Anthephora pubescens Ellis 1758 (8209)
Acid, sandy soils, hillsides.



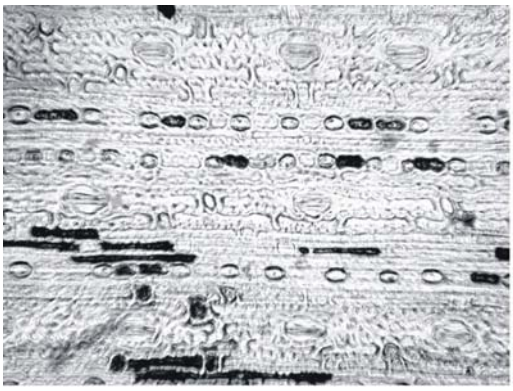
Anthoxanthum dregeanum Ellis 5494
(7795) Moist mountainslopes.



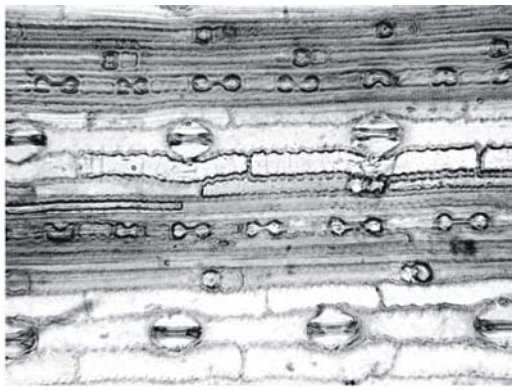
Aristida bipartita Ellis 285 (8036)
Moist areas, vleis.



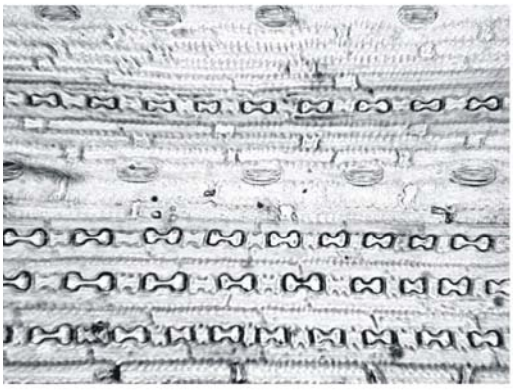
Aristida canescens subs. canescens Acocks
11424 (8038) Stony soils, rocky ridges.



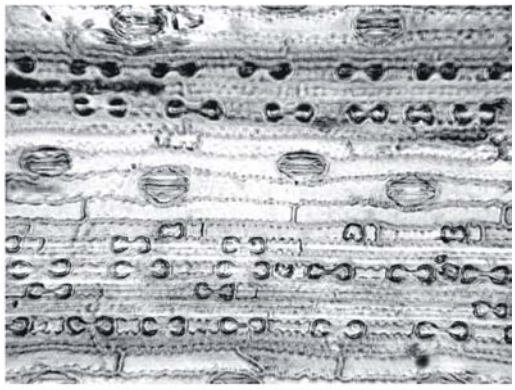
Aristida dasydesimis Pearson De Winter 3487 (8040) Granite slopes, arid areas.



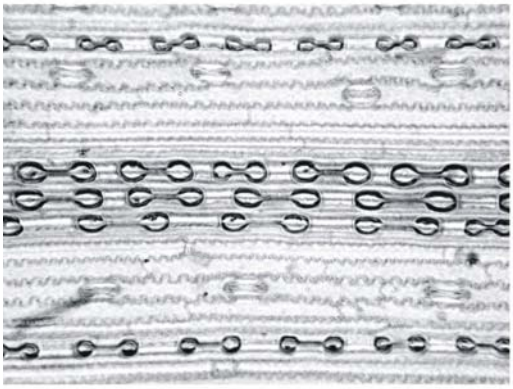
Aristida engleri Polevans De Winter 80 (8044) Rocky outcrops.



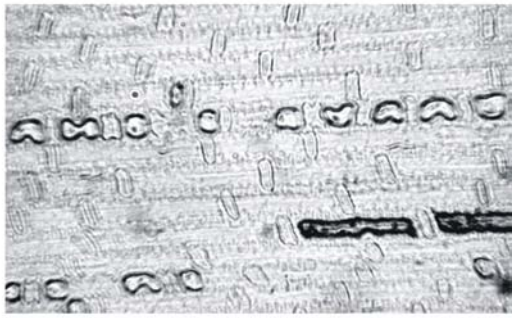
Aristida junciformis subs. galpinii Galpin De Winter 6900 (8046) High mountain terrain.



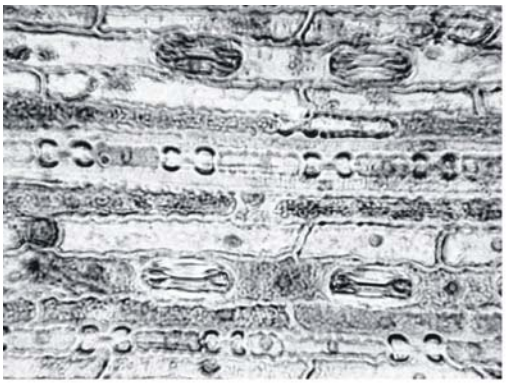
Aristida monticola Mogg De Winter 120634 (8048) Stream banks, mountain slopes.



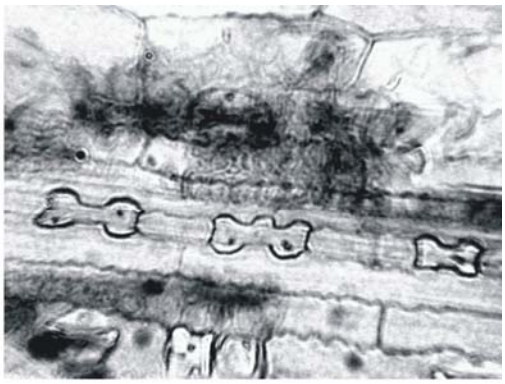
Aristida parvula De Winter 3474 (8050) Plains, along water courses.



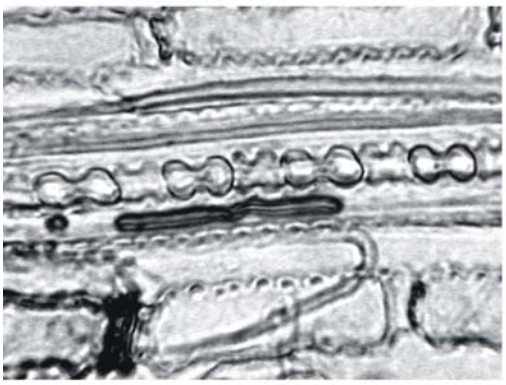
Aristida scuirus Pentz Acocks 10314 (8052) Moist sandy soils, mountain sourveld.



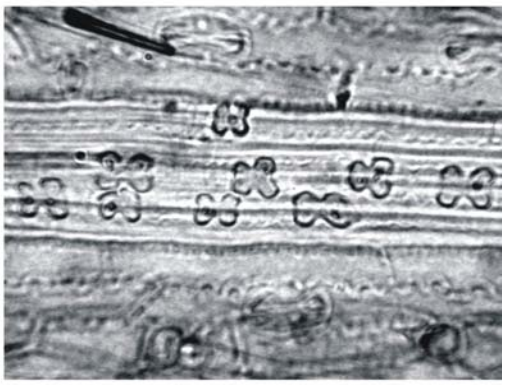
Bothriochloa bladhii Ellis 4473 (8214)
Riverbanks, vleis.



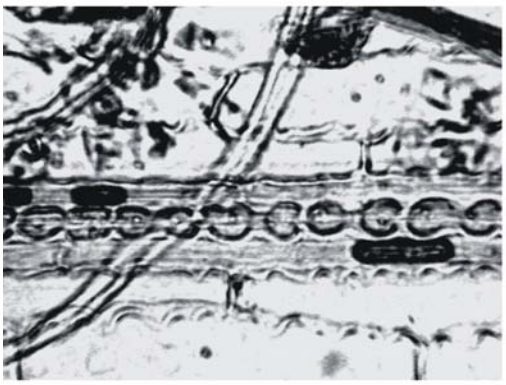
Bothriochloa insculpta Ellis 497 (8211)
Grassland, hillsides.



Brachiaria arrecta Ellis 3381 (8216) Vleis,
river floodplains, shallow water.

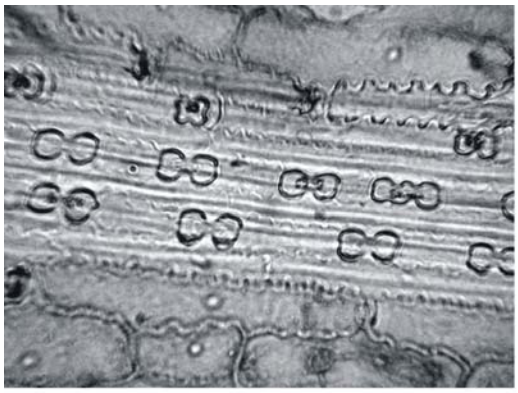


Brachiaria eruciformis Ellis 526 (8218)
Moist places.

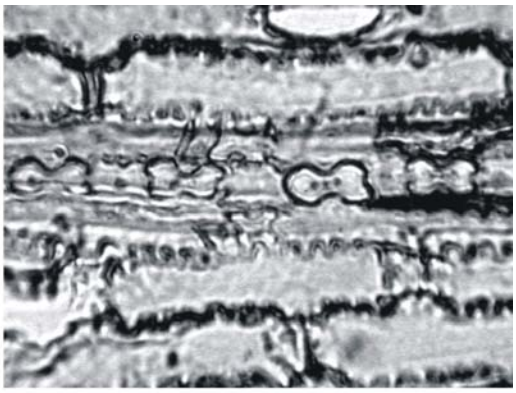


Brachiaria glomerata Ellis 3599 (8221)
Sandy soils, dunes, dry areas.

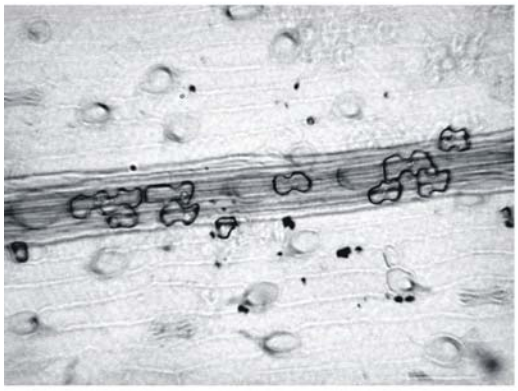
Brachiaria marlothi Ellis 3607 (8223)
Seasonally moist spots.



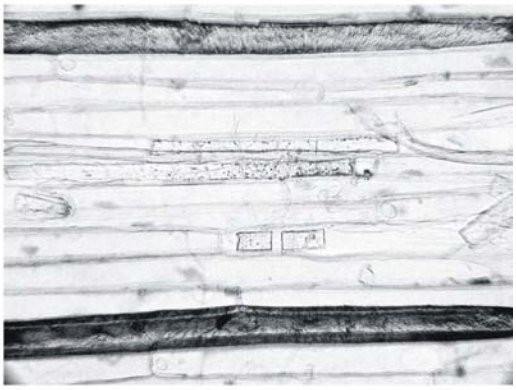
Brachiaria serrata Ellis 293 (8225)
Mountain slopes, grassland, vleis.



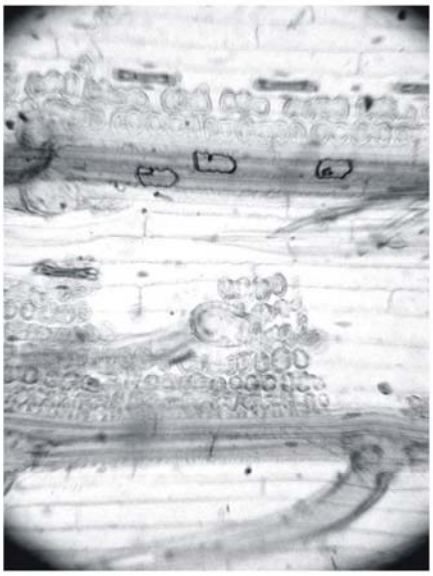
Brachiaria subulifolia Ellis 3535 (8228)
Damp, seepage areas.



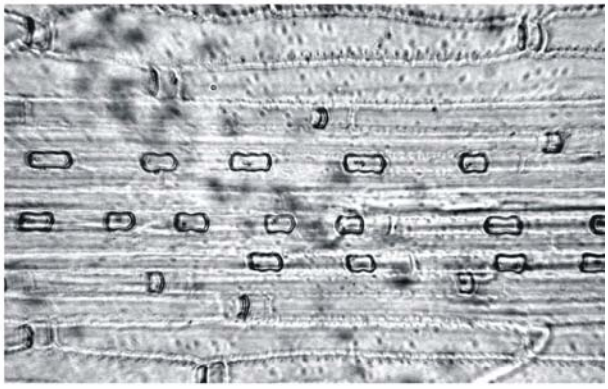
Brachypodium bolussi Ellis 2385 (7801)
Mountain grassland.



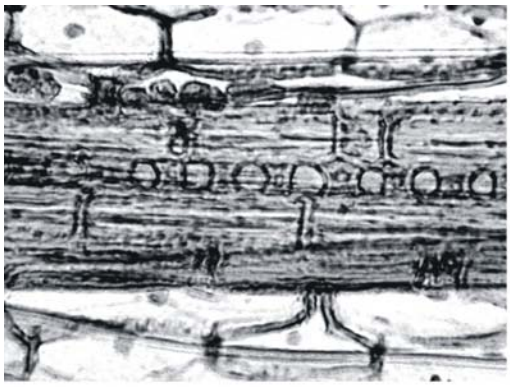
Bromus firmior Ellis 5702 (7803)
High alt., moist grassy mountain slopes.



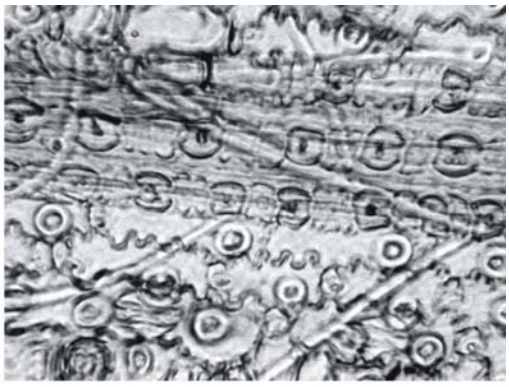
Bromus speciosus Ellis 2381 (7808)
Moist mountain slopes, shade,
along streams.



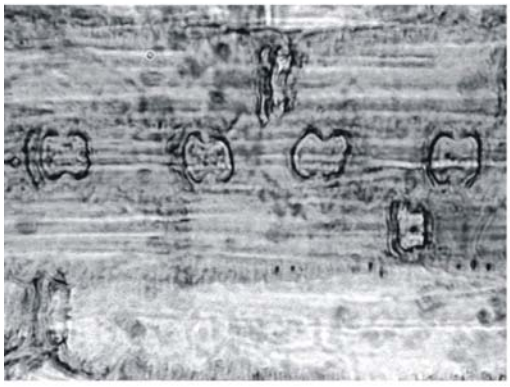
Chaetobromus dregeanus Ellis 2450 (8065)
Sandy, rocky, dry areas.



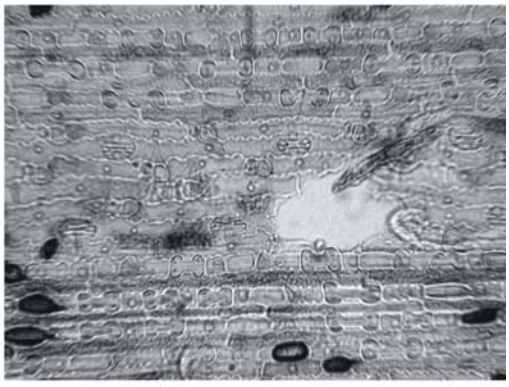
Chaetobromus involucratus Ellis 5345 (8063) Coastal areas, west coast.



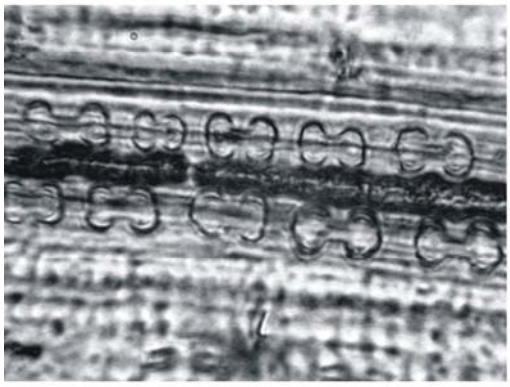
Chloris flabellata Ellis 4355 (8090) Coastal areas, saline marshes, flats.



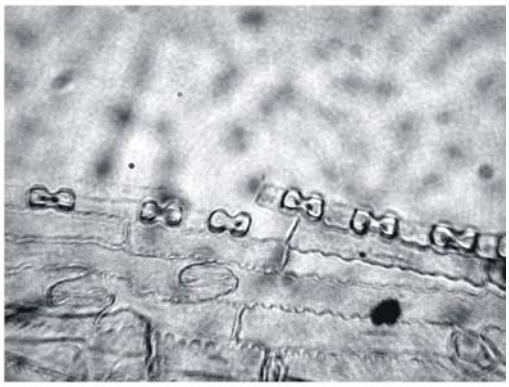
Coelarachis capensis Ellis 5194 (8488) Grassveld.



Ctenium concinnum Ellis 380 (8088) Open veld, moist soils.

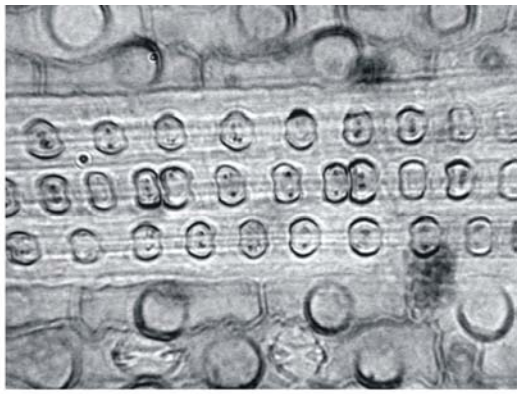


Cymbopogon excavatus Ellis 2047 (8237) Open veld, hillsides.

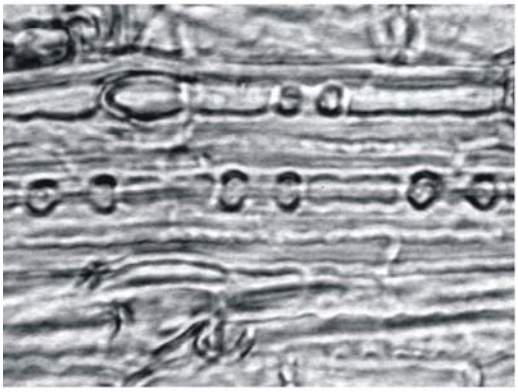


Cymbopogon marginatus van Heerden 29 (8234) Rocky hillsides, winter rainfall areas.

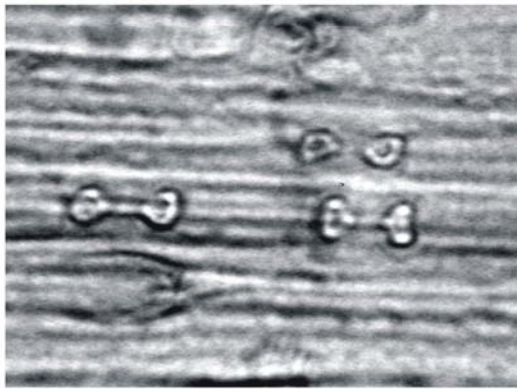
Cymbopogon plurinoides Ellis 3613
(8231) Grassveld.



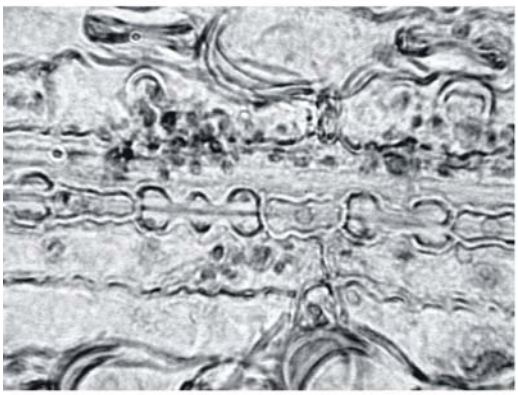
Dactyloctenium giganteum Ellis 529 (8096)
Oprnd veld, river banks, near water.



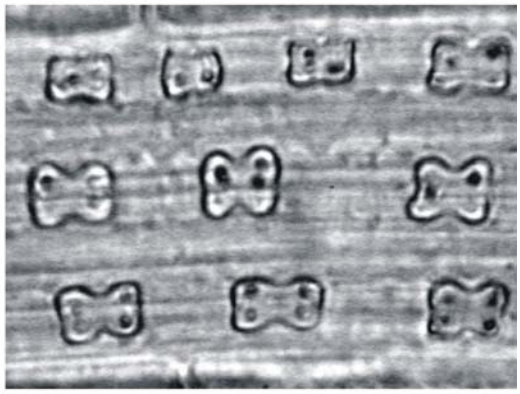
Dianthionopsis parva Ellis 1936
(8239) Rock crevices, cliffs.



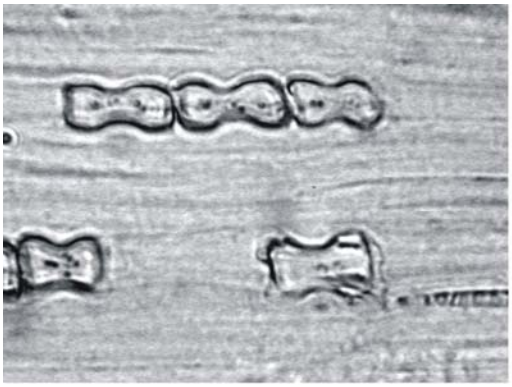
Diantionopsis pruinosa Ellis 1570 (8243)
Rock crevices on mountains.



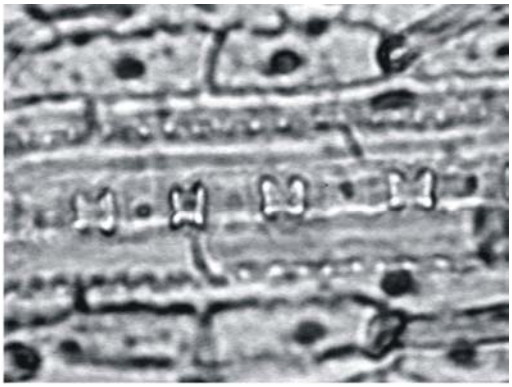
Dichantium annulatum Ellis 5251
(8248) Riverbanks, wet places.



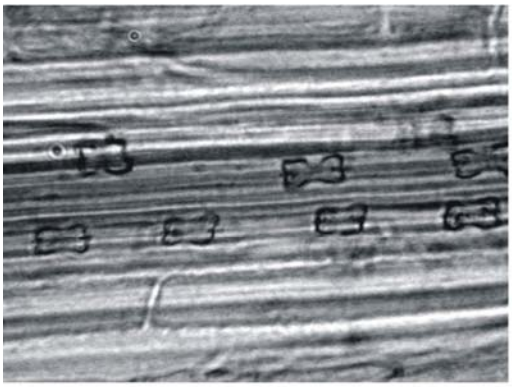
Digitaria brazzae de Wet 996
(8251) Grassland, hillsides.



Digitaria diagonalis Ellis 246 (8253)open, sourveld grassland, damp places.

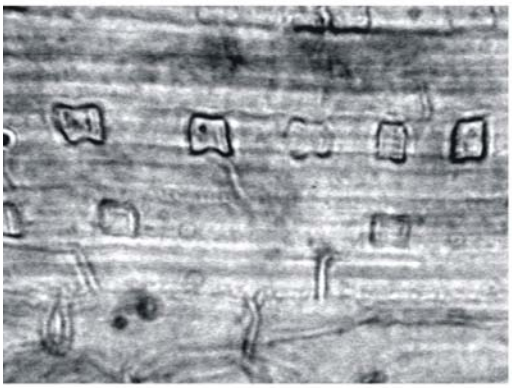


Digitaria diversinervis Ellis 4486 (8256) Sandy, coastal areas.

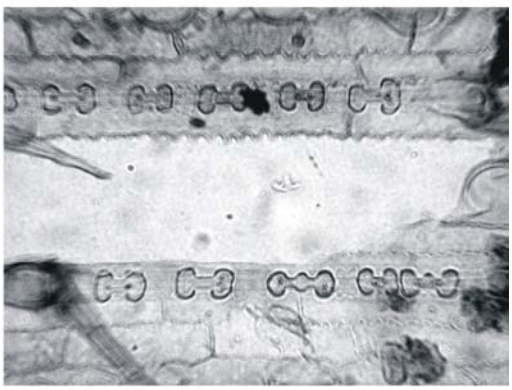


Digitaria monodactyla Ellis 147 (8258) Open grassland, highland sourveld.

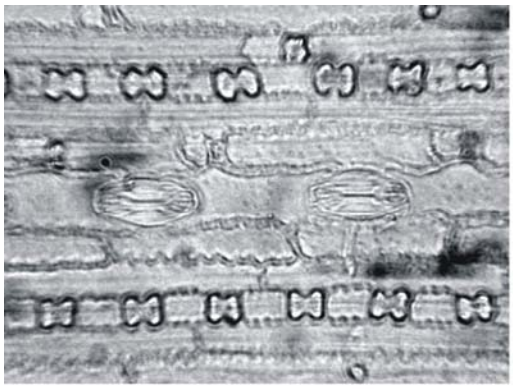
Digitaria setifolia Ellis 56 (8260) Mountain sourveld, damp places, vleis.



Digitaria ternata Ellis 39 (8263) Damp places.

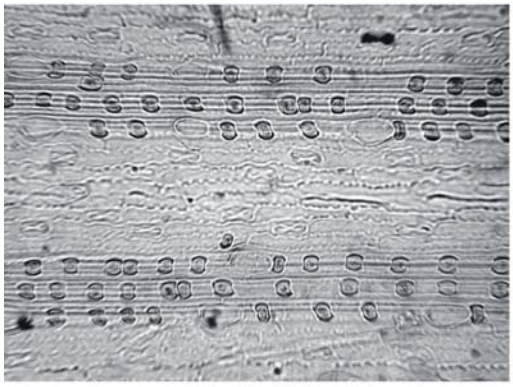


Diheteropogon amplectens Ellis 352 (8266) Stony slopes, woodland.

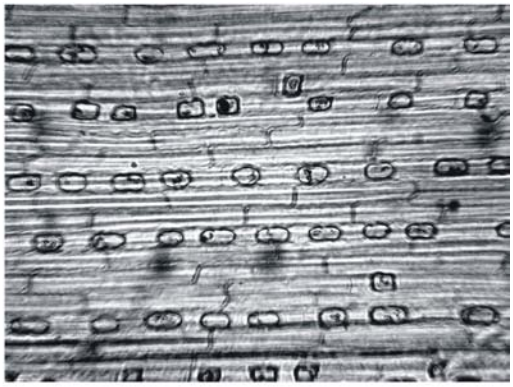


Diheteropogon filifolius Ellis 55 (8269)
Sour open grassveld, hilsides.

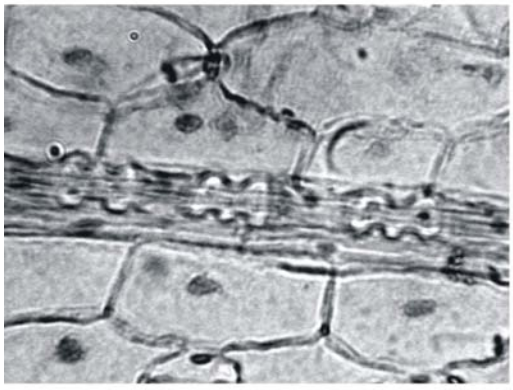
Dinebra retroflexa Ellis 3864 (8095)
Moist waterlogged soils, shade.



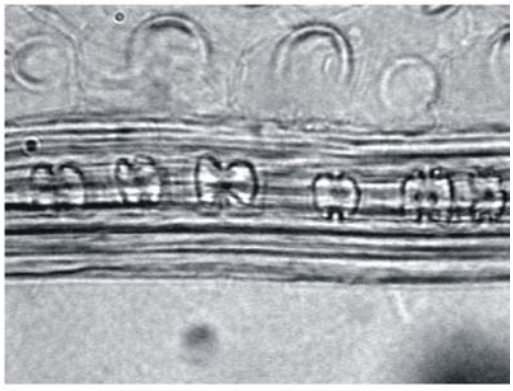
Diplachne eleusine de Wet 993 (8092)
Sandy soils, rocky slopes, shade.



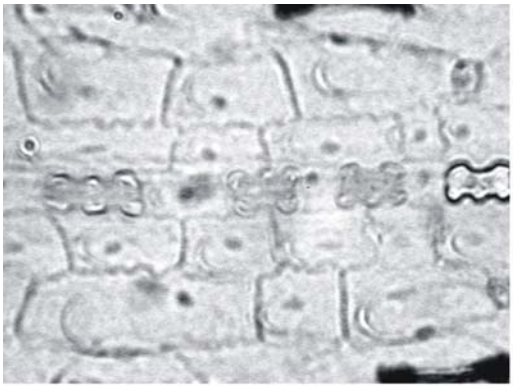
Dregechloa pumila Giess van Vuuren 653
(8058) Rocky areas, loose sand, arid areas.



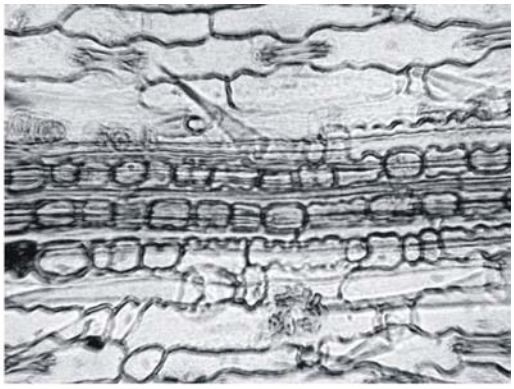
Echinochloa colona Ellis 3896 (8272)
Muddy, swampy places.



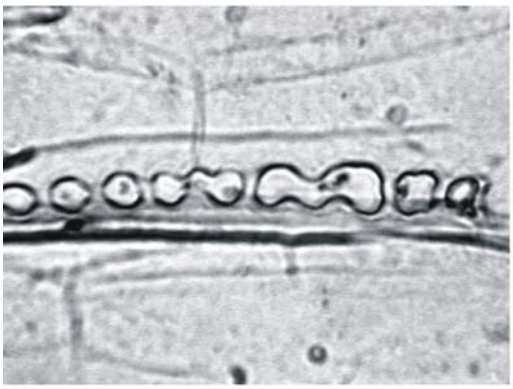
Echinochloa holubii de Wet 1005 (8276)
Swamps, vleis, pans.



Echinochloa stagnina Ellis 2910 (8278) standing water.

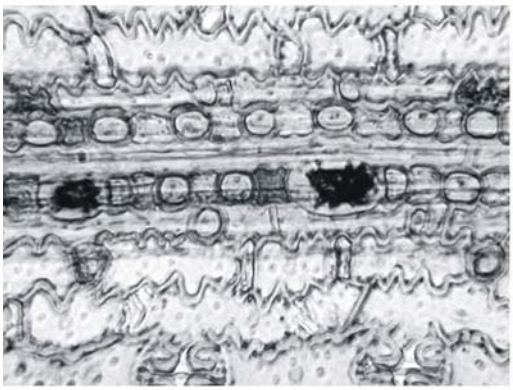


Ehrharta barbinoides Ellis 5409 (8154) Rocky hillsides, west coast.

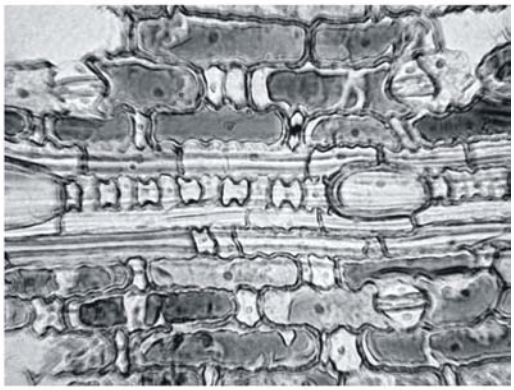


Ehrharta brevifolia subs. brevifolia Ellis 4641 (8159) Sandy soil, west coast.

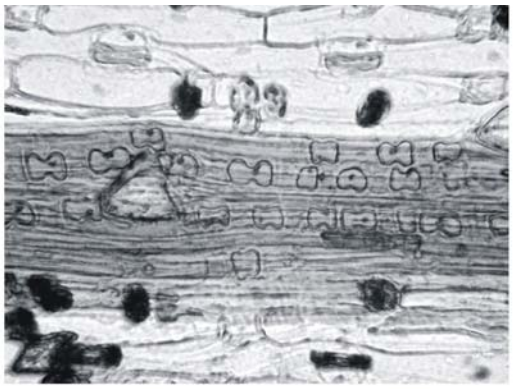
Ehrharta capensis subs. capensis Ellis 4691 (8160) Mountains, streamsides.



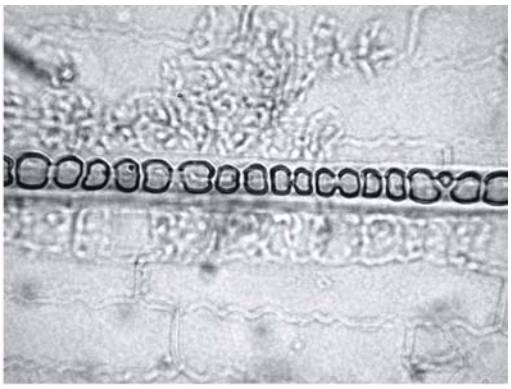
Ehrharta delicatula Ellis 4647 (8164) Mesic microhabitats in arid regions.



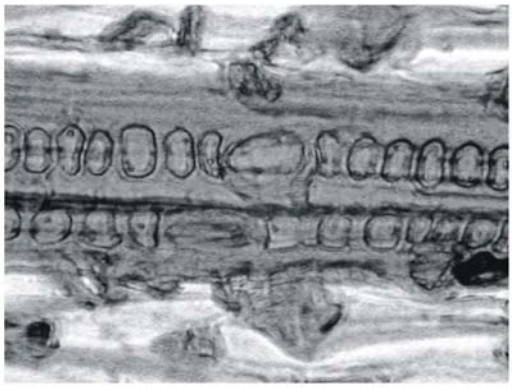
Ehrharta dura Ellis 5457 (8166) Mountain fynbos, seasonally moist open habitats.



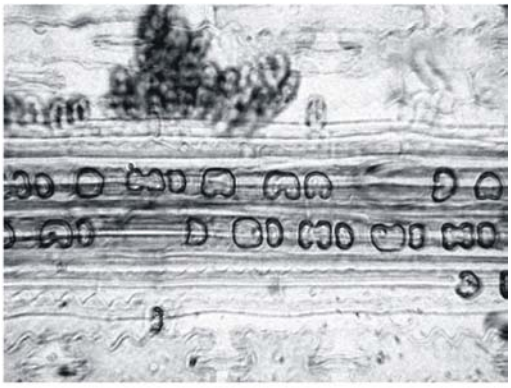
Ehrharta eburnea Ellis 5413 (8167)
Mountainsides, Rhenosterbosveld.



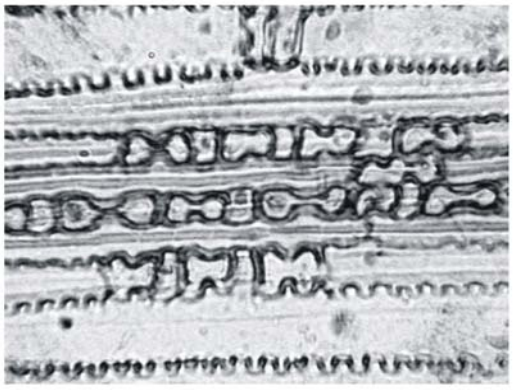
Ehrharta longiflora Ellis 1154 (8179)
Hillsides, shade, wet places.



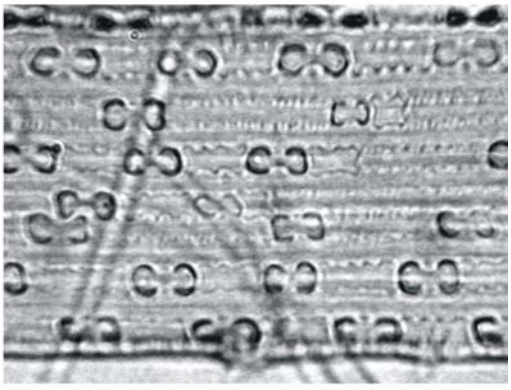
Ehrharta longigluma Ellis 5681
(8176) Mountain grassland.



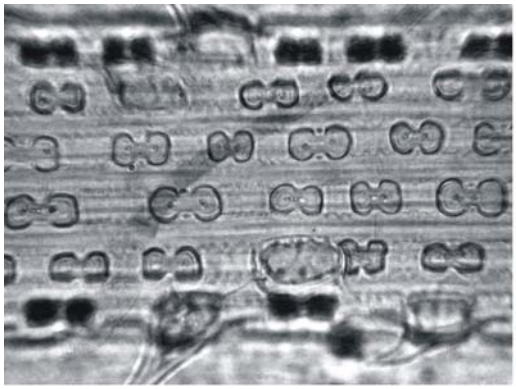
Ehrharta villosa 1700
(8187) Seaside dunes.



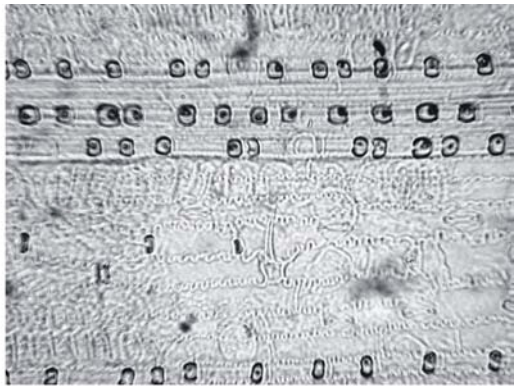
Elionurus muticus Ellis 5172 (8490)
Open grassland, sourveld.



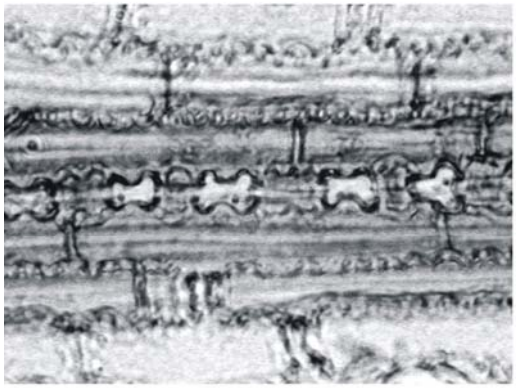
Enneapogon pretoriensis Ellis 1228
(8144) Rocky hillsides, grassveld.



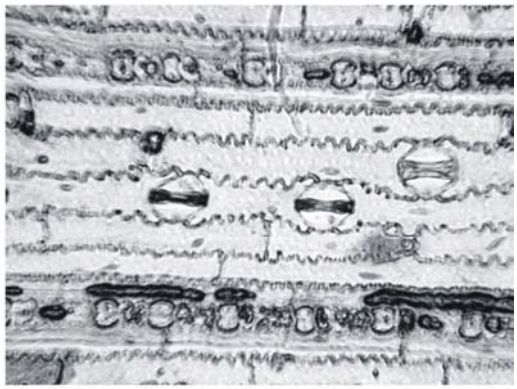
Enneapogon scaber Ellis 1625 (8143) Rock crevices, plains, dry sandy riverbeds.



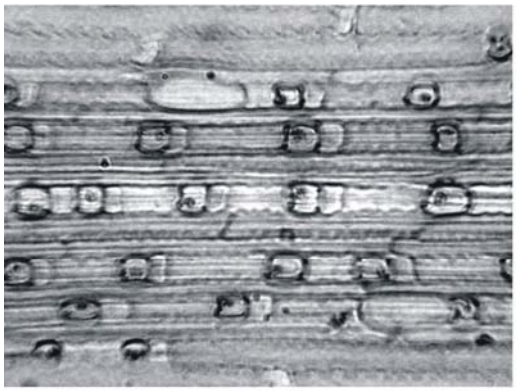
Entolasia imbricata PA Smith 1876 (8282) Floodplains, seasonally flooded to 1m.



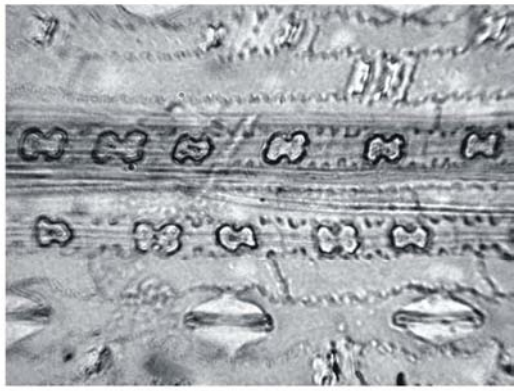
Entoplacamia aristulata de Wet 964 (8097) Rocky outcrops, open plains.



Eragrostis bicolor Ellis 3652 (8100) Wet places, in water, seasonal pans.

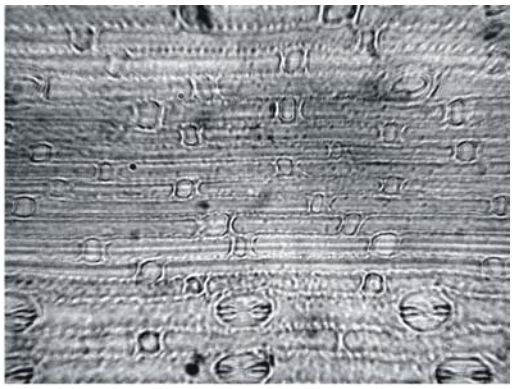


Eragrostis biflora Ellis 1610 (8102) Moist areas, under trees.

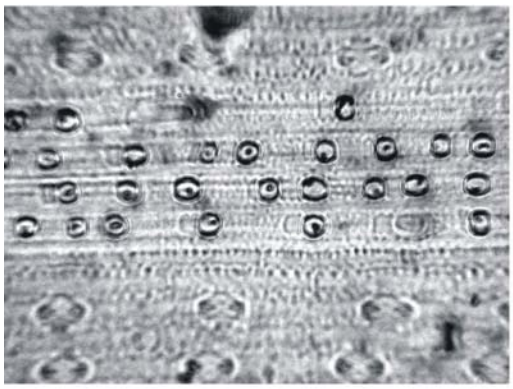


Eragrostis brizantha Ellis 1349 (8104) Sandy, calcareous soils around rivers.

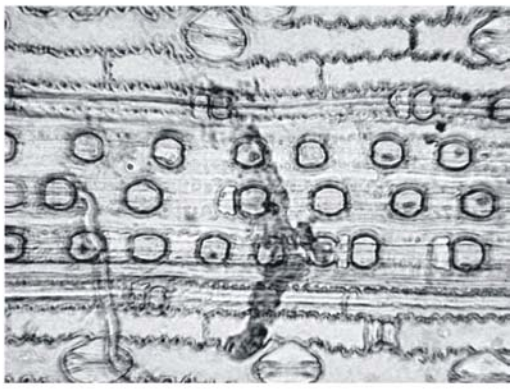
Eragrostis chloromelas Ellis 752
(8106) Hillslopes, rocky ridges.



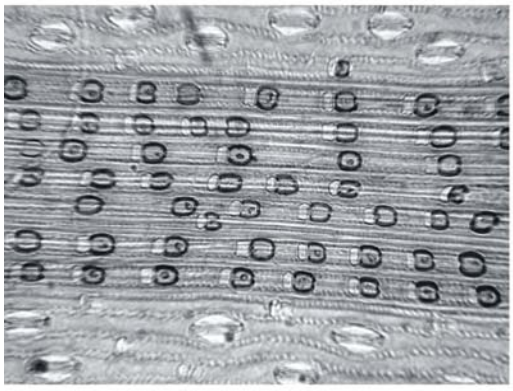
Eragrostis eliator van Heerden 71 (8109)
Riverbanks, periodically inundated areas.



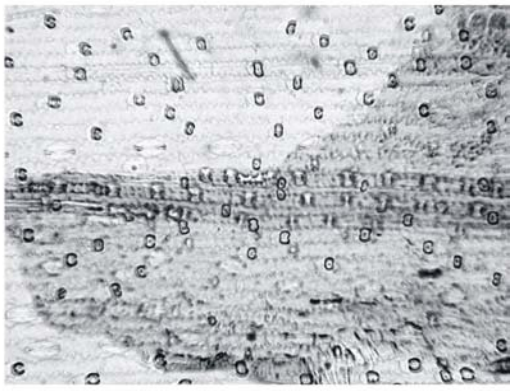
Eragrostis kingesii de Wet Hardy
7872 (8111) Arid regions.



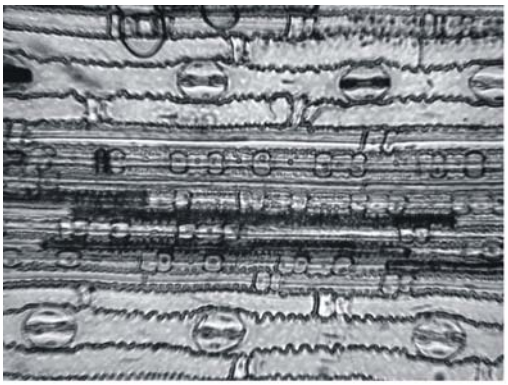
Eragrostis macrochlamys Gibbs Russel
Smook 5436 (8113) Arid areas.



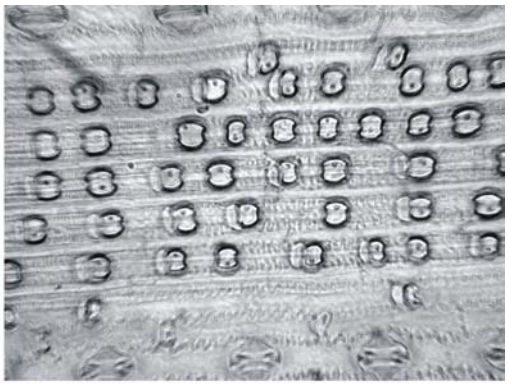
Eragrostis obtusa Ellis 2093
(8114) Open veld.



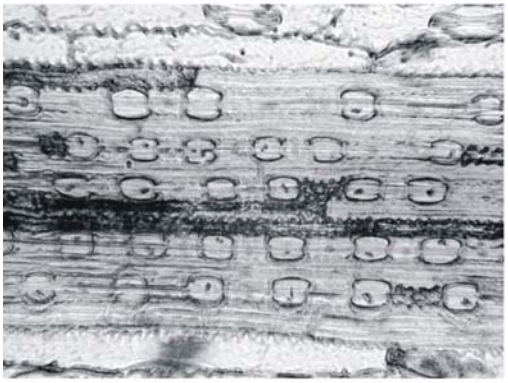
Eragrostis pilgeriana De Wet 2464 (8117)
Calcareous soils with high moisture content.



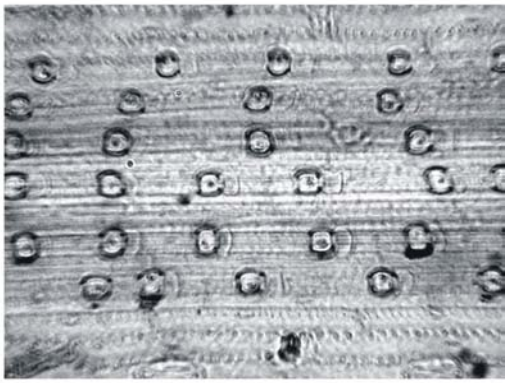
Eragrostis planiculmis Ellis 3330 (8118) Depressions, vlei margins.



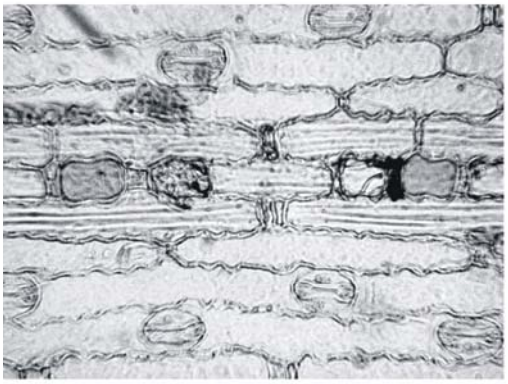
Eragrostis pseudo-obtusa Ellis 838 (8120) Moist areas, along streambeds.



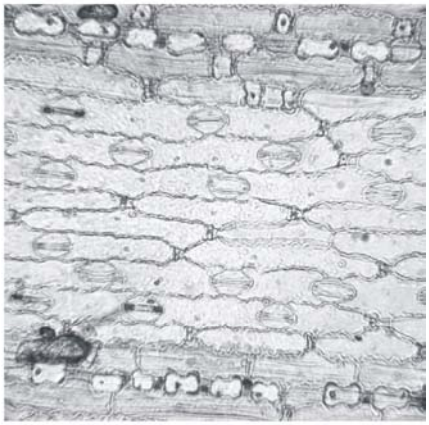
Eragrostis remotiflora Ellis 3666 (8121) Damp, wet places, pans, vleis.



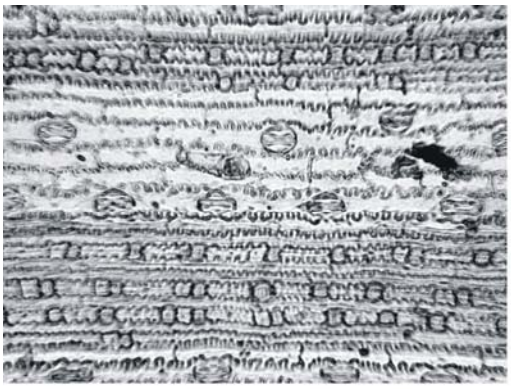
Eragrostis truncata Ellis 3647 (8124) Limestone soils, pans.



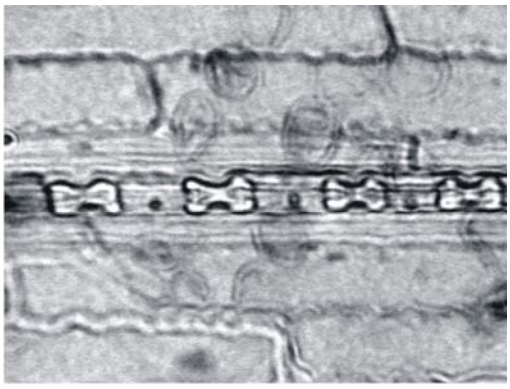
Eragrostis walteri Ellis 4345 (8127) Damp brackish soils, seepage areas, running water, arid regions.



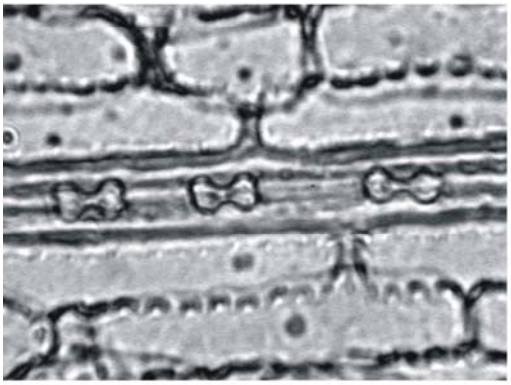
Eragrostis walteri Ellis 4352 (8126) Damp brackish soils, seepage areas, running water, arid regions.



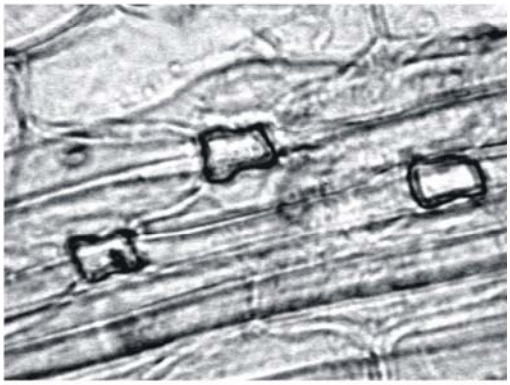
Eragrostis walteri Ellis 4759 (8125) Damp brackish soils, seepage areas, running water, arid regions.



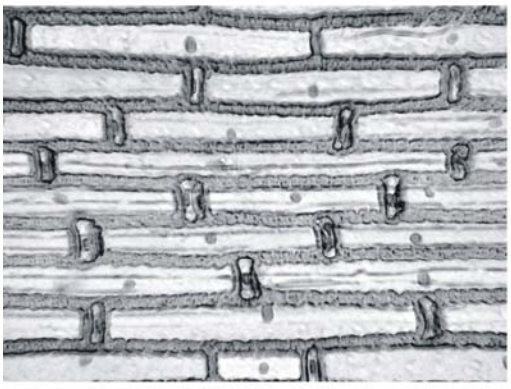
Eriochloa meyeriana Ellis 536 (8285) Riverbanks, wet places.



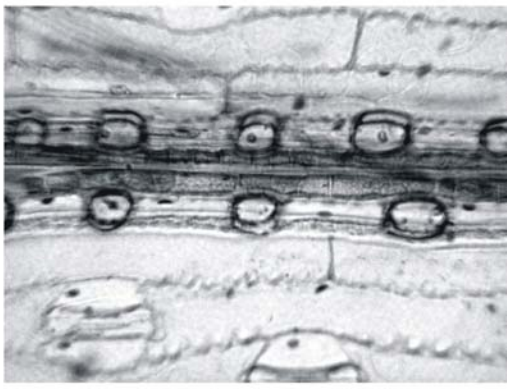
Eriochloa stapfiana Ellis 5248 (8289) Riverbanks, wet places.



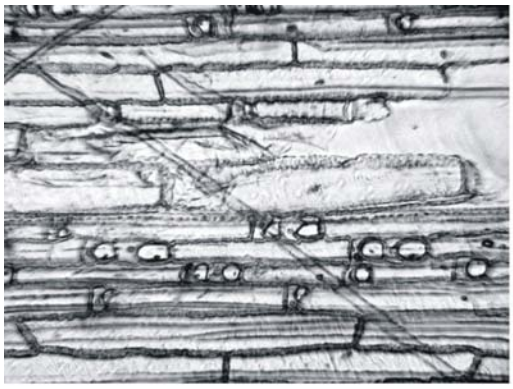
Eriochrysis pallida Ellis 5198 (8293) Vleis, riverbanks.



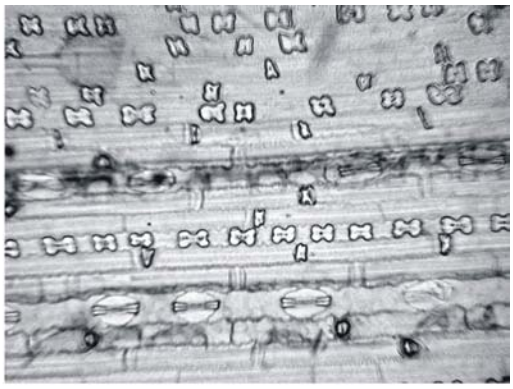
Festuca killicki Ellis 5717 (7817) High alt. subalpine grassveld.



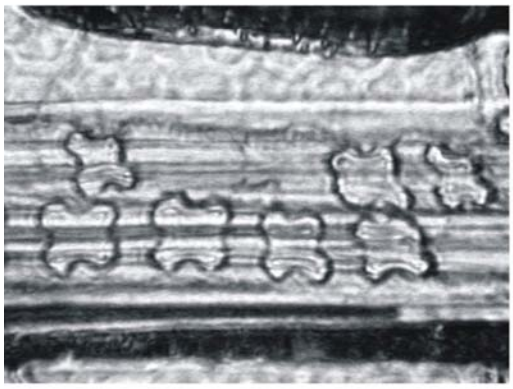
Festuca longipes Ellis 2608 (7821) Steep grassy mountain slopes.



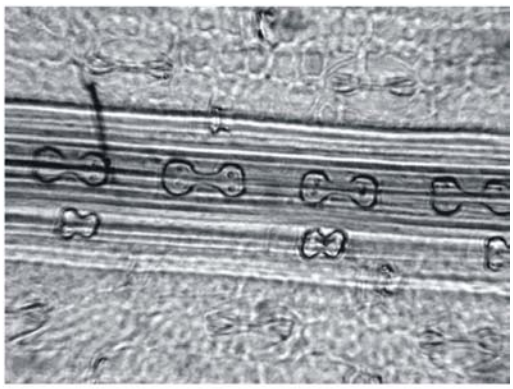
Helictotrichon longifolium Ellis 5676 (7832)
Moist, rocky mountain slopes.



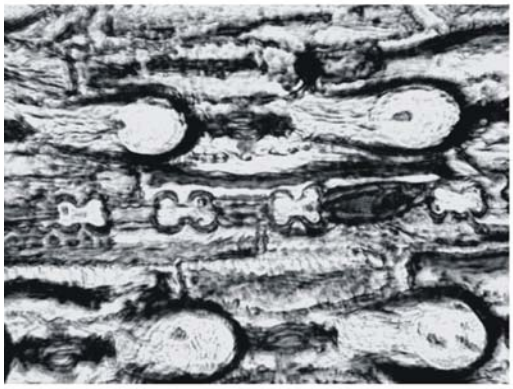
Helictotrichon turgidulum Ellis 71 (7838)
Wet places on mountain slopes, vleis.



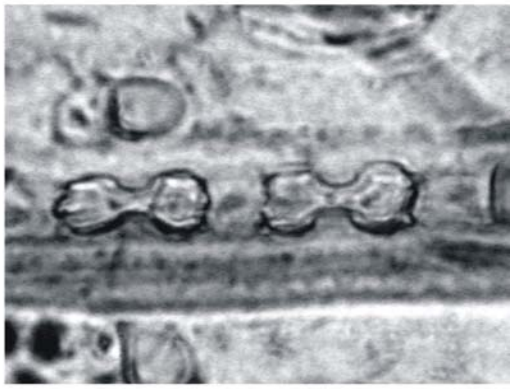
Hemarthria altissima de Wet 1020
(8493) Vleis, river margins.



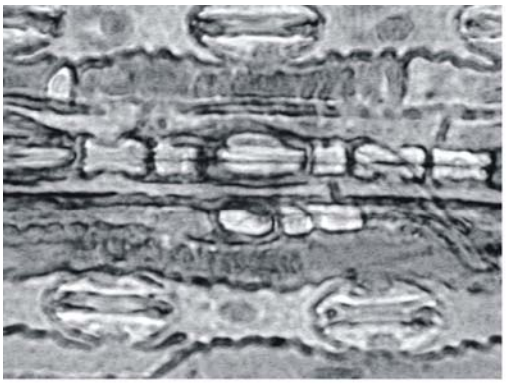
Heteropogon contortus Ellis 1169 (8299)
Open veld, hilsides, rocky places



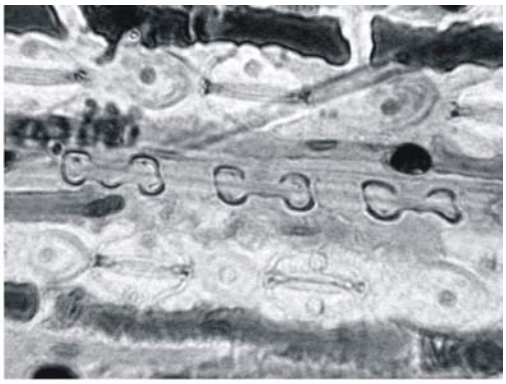
Hyperhenia anamesa Ellis 1649
(8301) Dry soils, open veld.



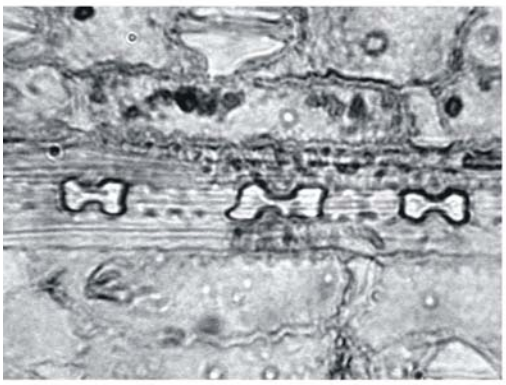
Hyperhenia dregeana R Manders no
nr (8304) Dry soils around vleis.



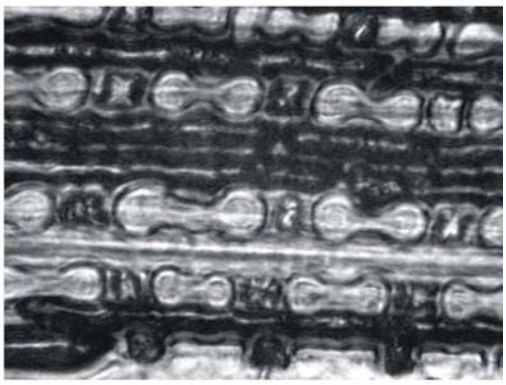
Hyperhenia tamba Ellis 784
(8309) Streamsides.



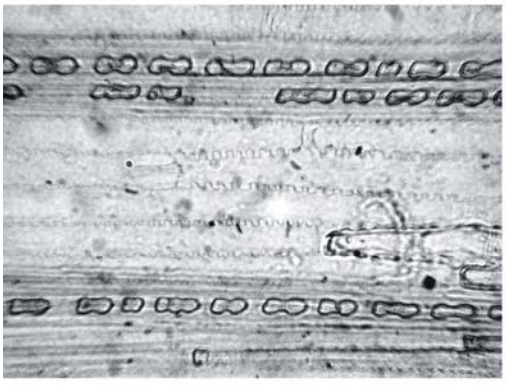
Hyperthelia dissolata Ellis 1513
(8312) Open veld.



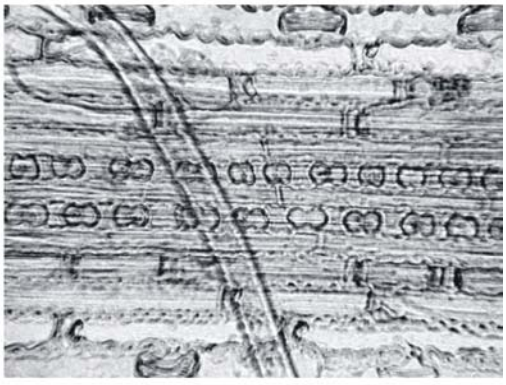
Imperata cylindrica Ellis 1336 (8315)
Riverbanks, vleis, seasonally wet places.



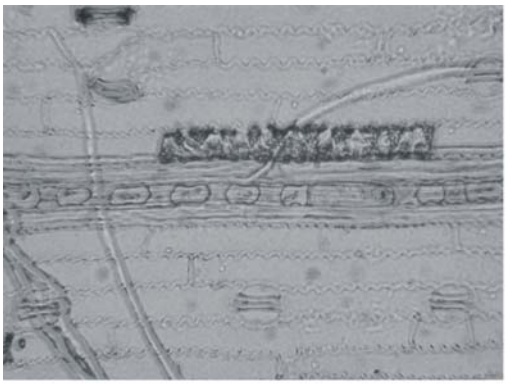
Ischaemum afrum Ellis 505 (8319)
Black turf soil, usually near water.



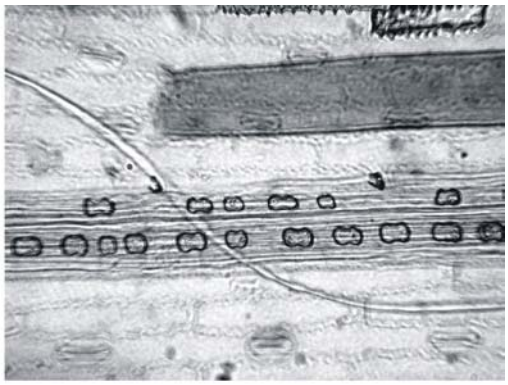
Karroochloa curva Ellis 2570 (8071)
Damp shady habitats.



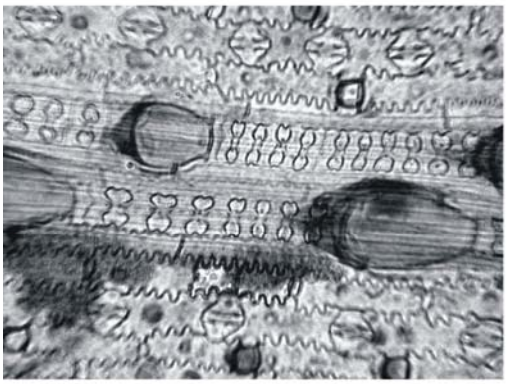
Karroochloa purpurea Ellis 5703 (8073)
Mountainous areas, short grasslands.



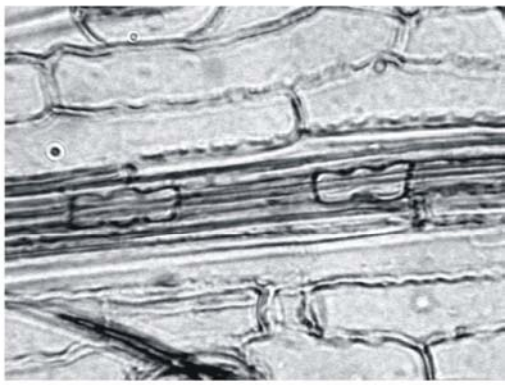
Karroochloa schismoides Ellis 5068 (8069) Dry mountains.



Karroochloa tenella Leistner 470 (8067) Sandy soils, dry regions.

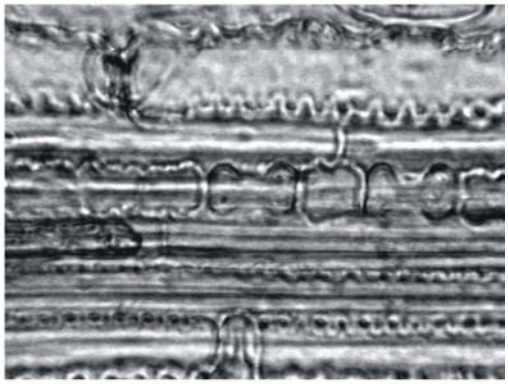


Leersia hexandra Ellis 228 (8150) Floodplains, vleis, pans.

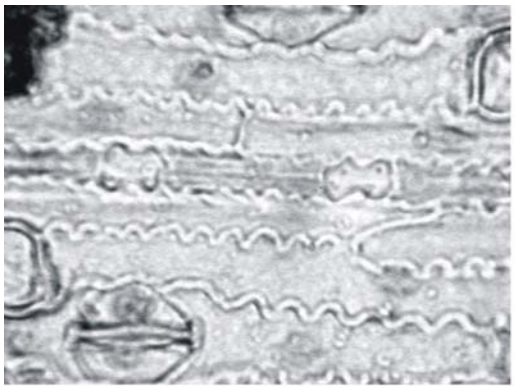


Leucophrys mesocoma Ellis 892 (8322) Sandy riverbeds.

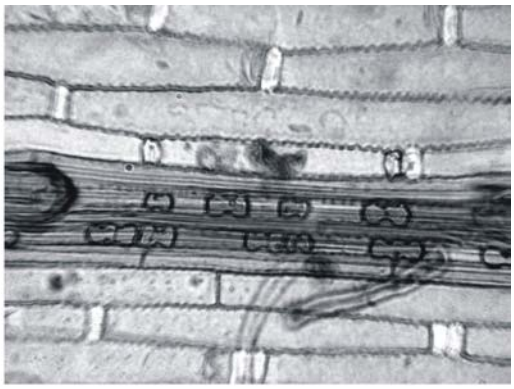
Loudetia flavida Ellis 978 (8327) Rocky soils, vlei margins.



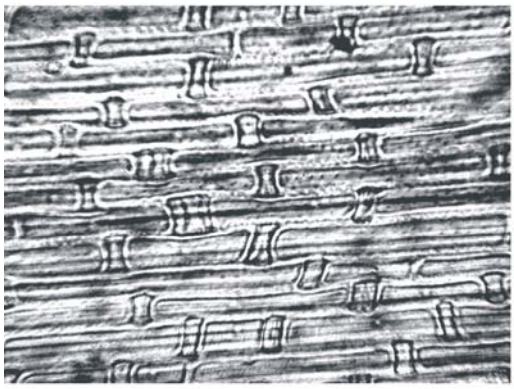
Loudetia simplex Ellis 3376 (8329) Open grassland, hillsides.



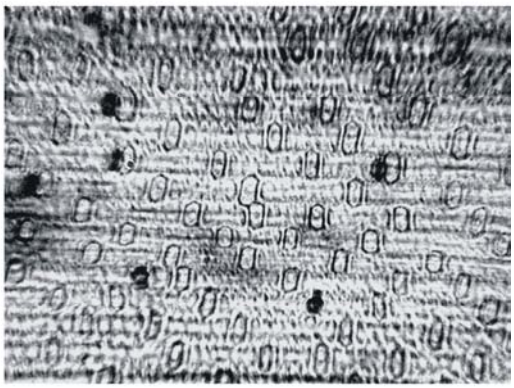
Melenis minutiflora Ellis 3798 (8334) Moist, shady areas, sand or near rocks.



Melica decumbens van Heerden 86 (7848) Hillsides, mountainsides, shade under trees.



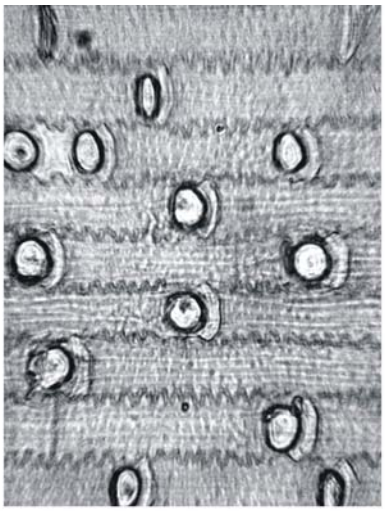
Merxmuellera arundinaceae Ellis 1149 (7910) Xeric areas, Cape fold mountains.



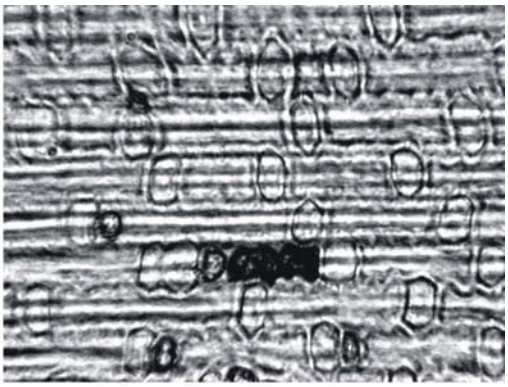
Merxmuellera aureocephala Ellis 3137 (7911) High alt. xeric areas, Drakensberg mountains.

Merxmuellera cincta Ellis 2332 (7913) Moist areas, mountain slopes.

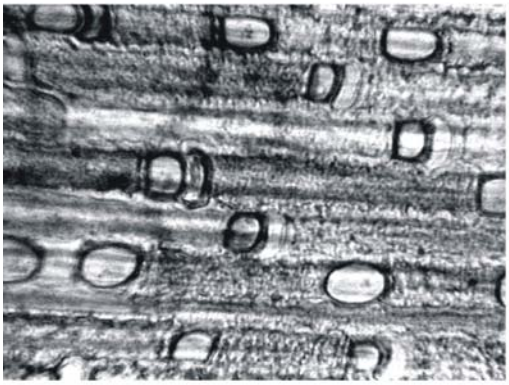
Merxmuellera decora Ellis 657 (7916) Sandy soils, Cape mountain slopes.



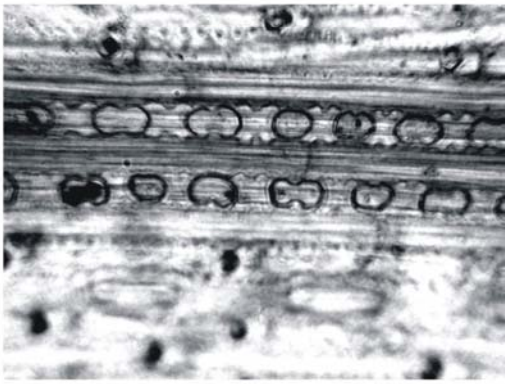
Merxmuellera disticha Loxton 246 (7918) Coastal regions, high alt. mountain regions.



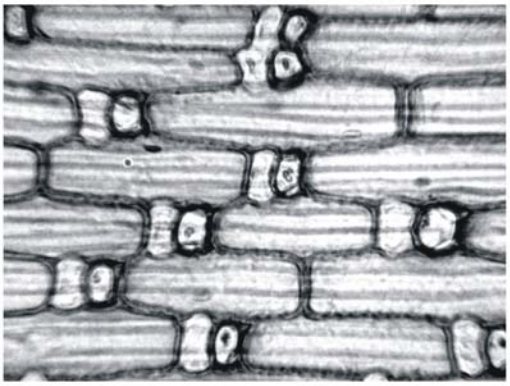
Merxmuellera drakensbergensis Ellis 997 (7920) Mesic sites, streamsides, alpine belt.



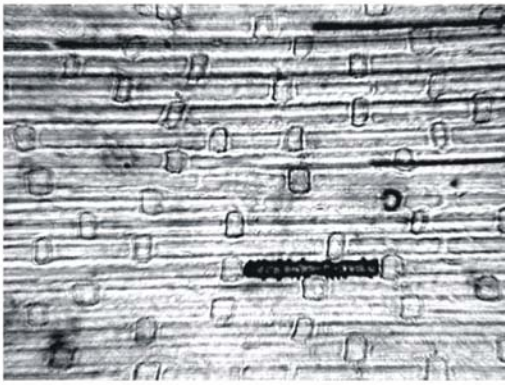
Merxmuellera dura Ellis 2455 (7924) Stony, sandy soils, arid areas.



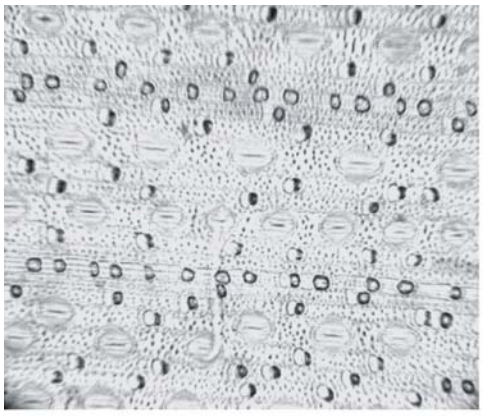
Merxmuellera guillarmodiae Killick 110 (7927) Alpine grassland, moist places.



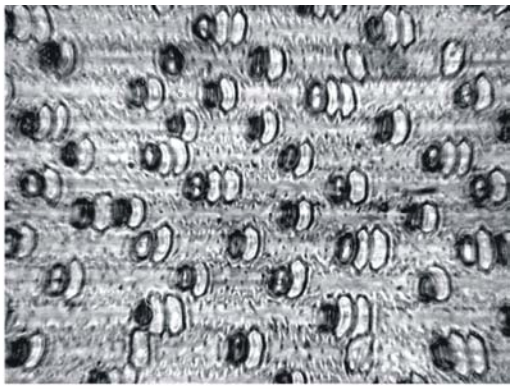
Merxmuellera lupulina Ellis 2255 (7935) Sandy mountain slopes, southwestern Cape mountains.



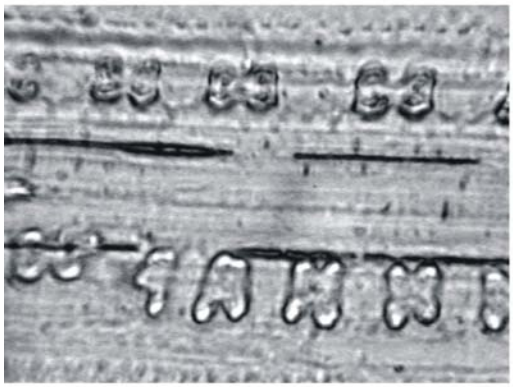
Merxmuellera macowanii Edwards 2673 (7930) Montane, subalpine regions.



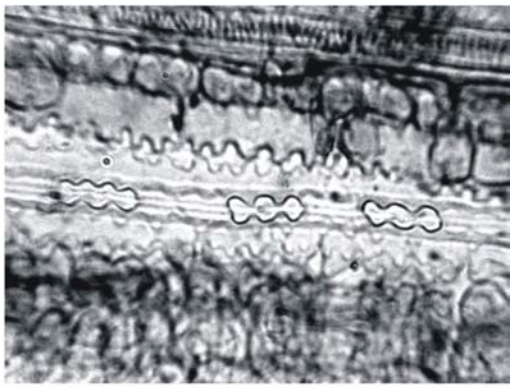
Merxmuellera rangei Schlieben 11599 (7932) Dry sandy ares between hills and koppies.



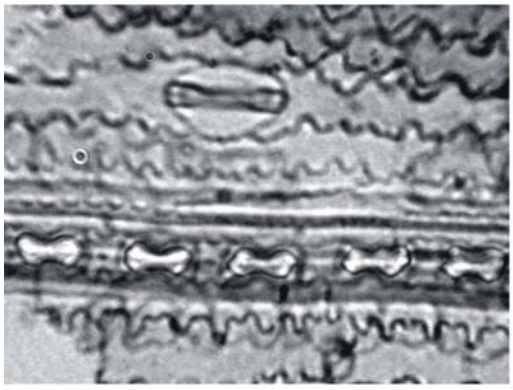
Merxmuellera stereophylla Ellis 3139 (7939) Xeric alpine graaslands, Drakensberg range.



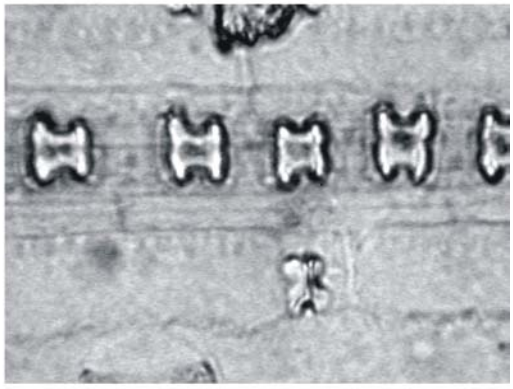
Monocymbium ceresiiforme de Wet 1036 (8340) Open grasslands, hillsides.



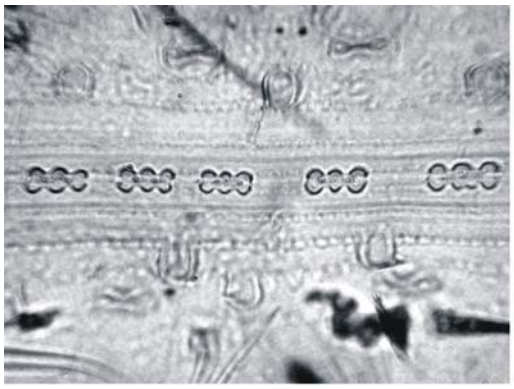
Oplismenus hirtellus Ellis 282 (8345) Forest shade.



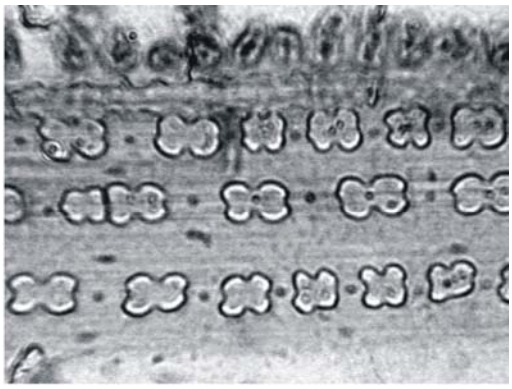
Oplismenus hirtellus Ellis 282 (8349) Forest shade.



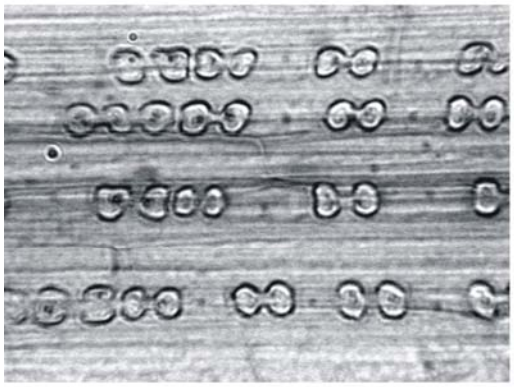
Panicum coloratum Ellis 1783 (8357) Riverbeds, drainages, pans.



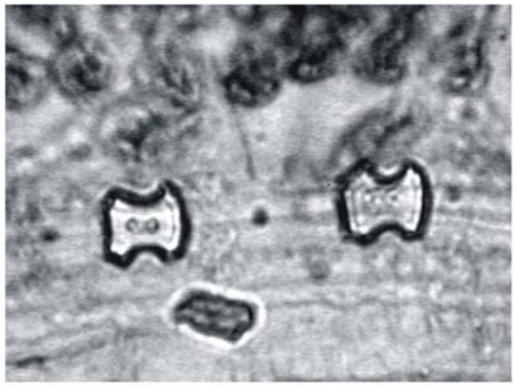
Panicum deustum Ellis 1547 (8360)
Moist soils, shade, rocky hillsides.



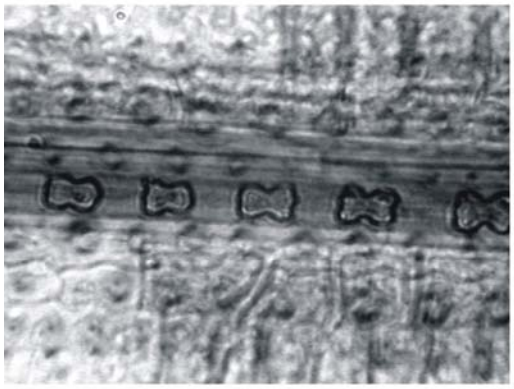
Panicum ecklonii Ellis 1421 (8366)
Moist areas in mountainous regions.



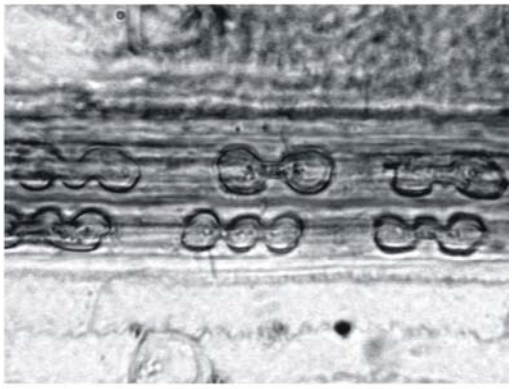
Panicum heterostachyum Ellis 1923 (8367)
Sandy soils in wooded grassland,
seasonally flooded pans.jpg



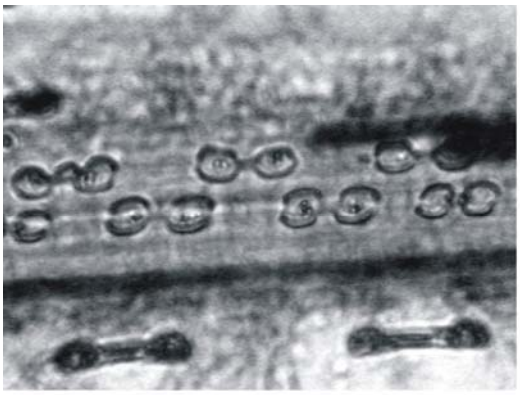
Panicum hymeniochilum Ellis 1560 (8369) Moist,
organically rich soils, river margins, swamps.jpg



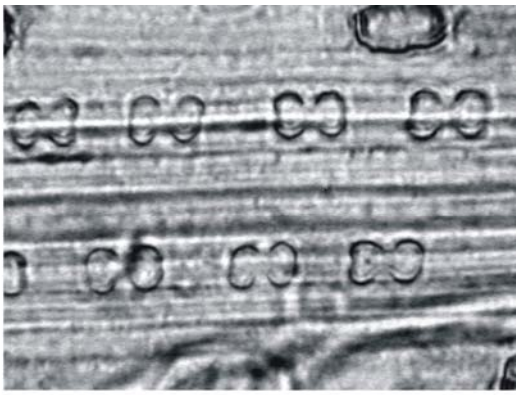
Panicum impeditum Ellis 2918
(8373) Vleis, pans.



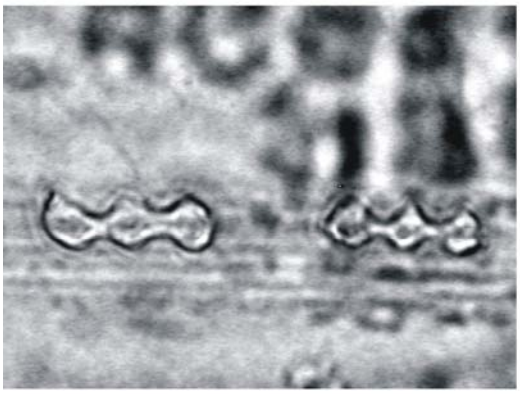
Panicum infestum Ellis 1308 (8375)
Seasonally damp places, hillsides.



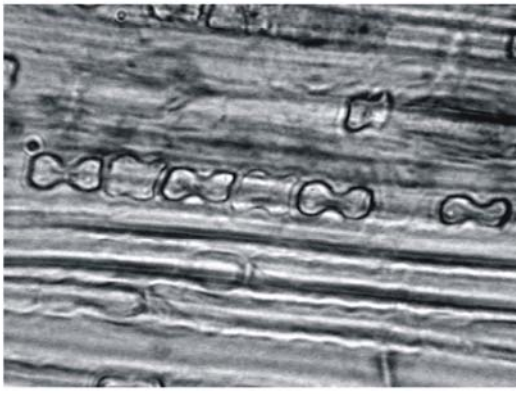
Panicum laticomum Ellis 3231 (8387)
Sandy soils in forests.



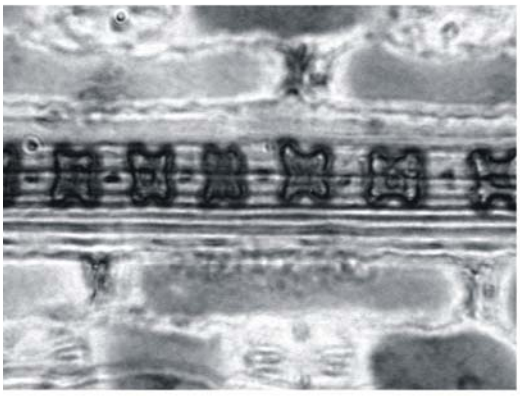
Panicum maximum Ellis 67 (8388)
Shady places, river margins.



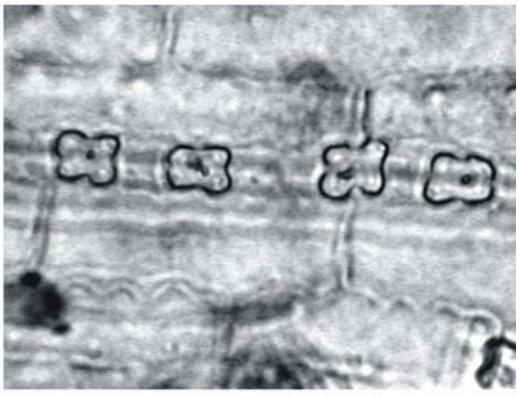
Panicum monticola Ellis 1869 (8390)
Forest, shade.



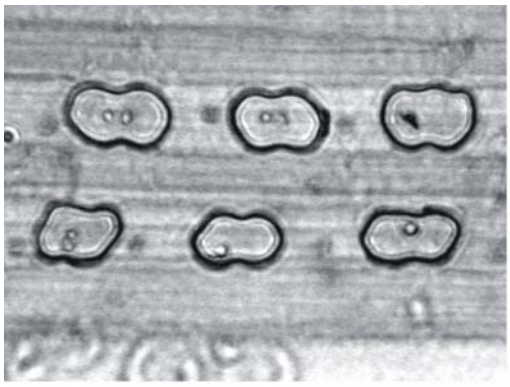
Panicum natalense Ellis 453 (8391) Open
veld, shallow soils in rocky areas.



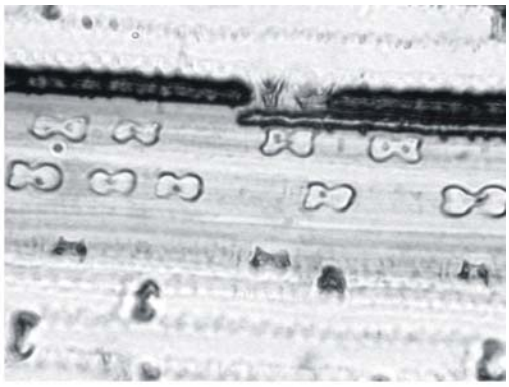
Panicum repens Ellis 2912
(8396) Wet sandy soils.



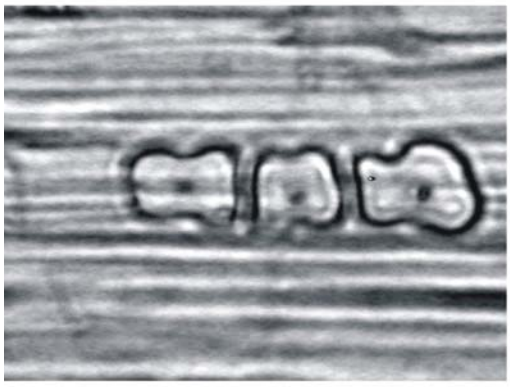
Panicum stapfianum van Heerden
90 (8400) Damp or dry areas.



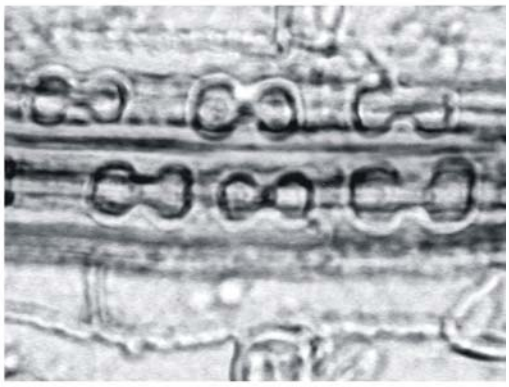
Pennisetum glaucocladum Ellis 2922 (8406) Riverbanks, wet areas.



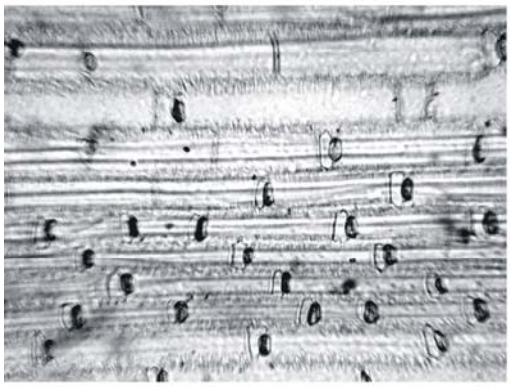
Pennisetum sphacelatum de Wet 8687 (8413) Wet areas, vleis.



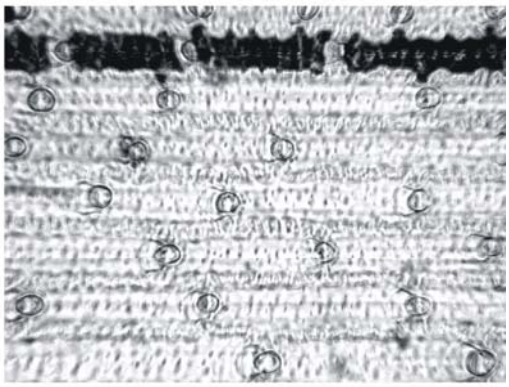
Pennisetum thunbergi Ellis 227 (8416) Wet places, vleis, river banks.



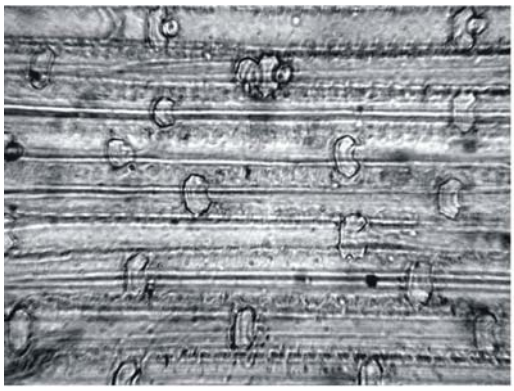
Pennisetum unisetum Ellis 4976 (8418) Near water, shade.



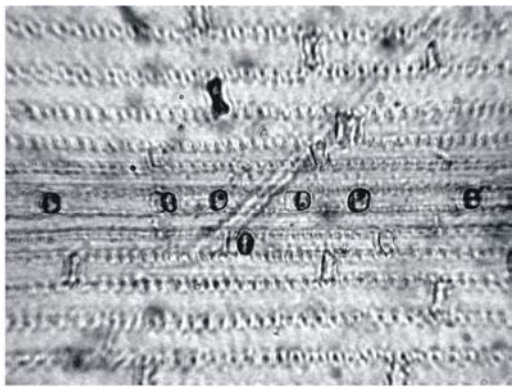
Pentameris dregeana Ellis 2495 (8027) Rock crevices, Cape fold mountains.



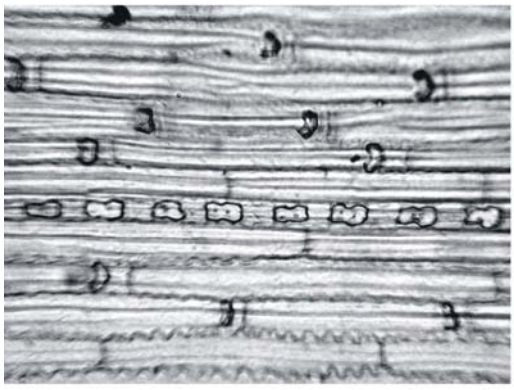
Pentameris macrocalycina Ellis 2500 (8029) Rock crevices, Cape fold mountains.



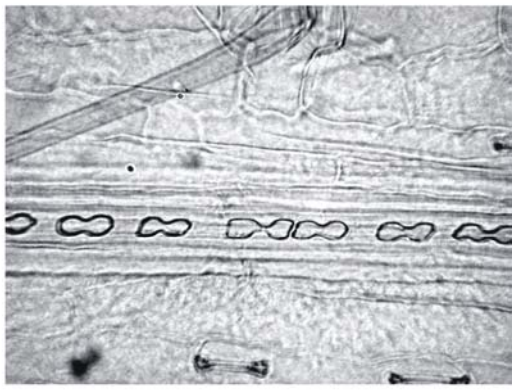
Pentameris obtusifolia Esterhuysen 27442 (8031) Mountain slopes, Hottentots Holland Mountains.



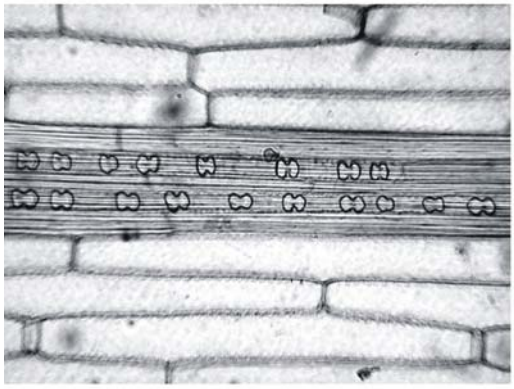
Pentameris thuari Barker 7653 (8033) Seeps, river banks.



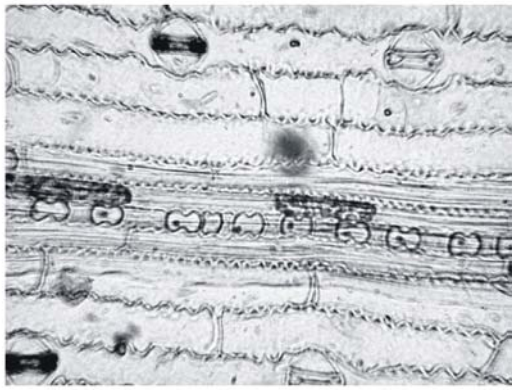
Pentaschistis acinosa Ellis 2267 (7941) Sandstone rock crevices Cape.



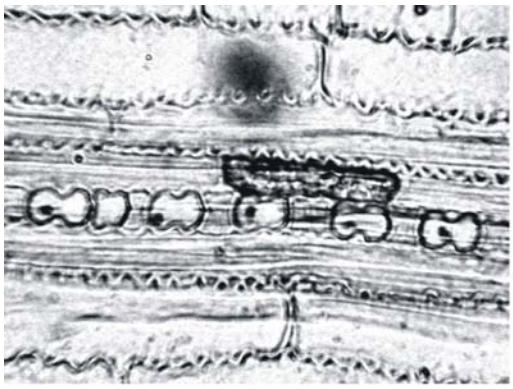
Pentaschistis airoides Ellis 2555 (7944) Rich soils, fynbos.



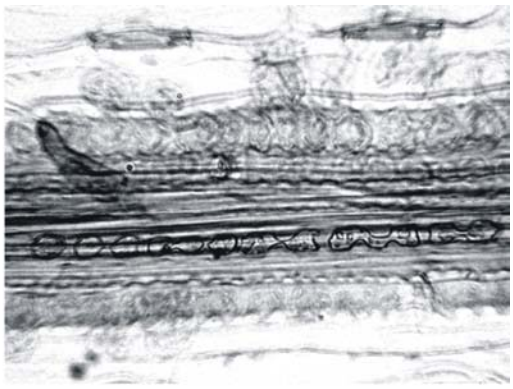
Pentaschistis ampla Esterhuysen 28112 (7946) Low to mid-altitudes on sandstone-derived soils.



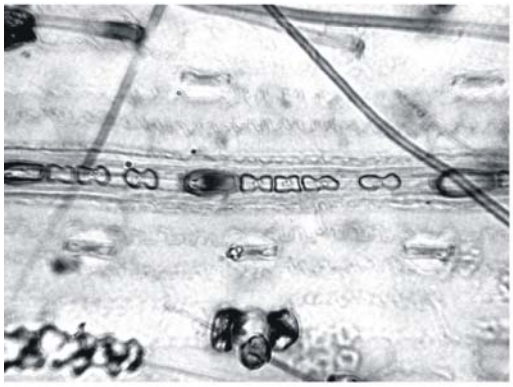
Pentaschistis aristifolia Ellis 5781 (7951) Dry Karoo sediments.



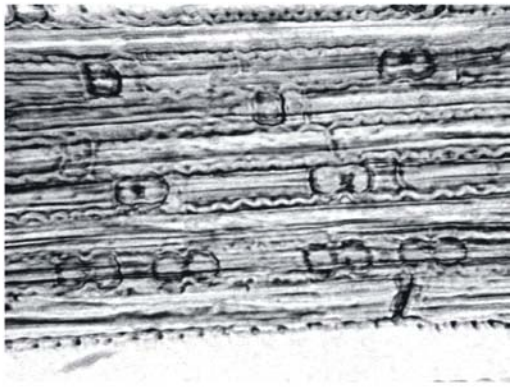
Pentaschistis aristifolia Ellis 5781
(7952) Dry Karoo sediments.



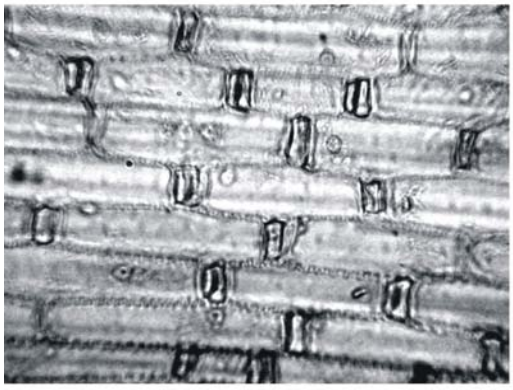
Pentaschistis aspera Ellis 2305
(7954) Stony slopes, fynbos.



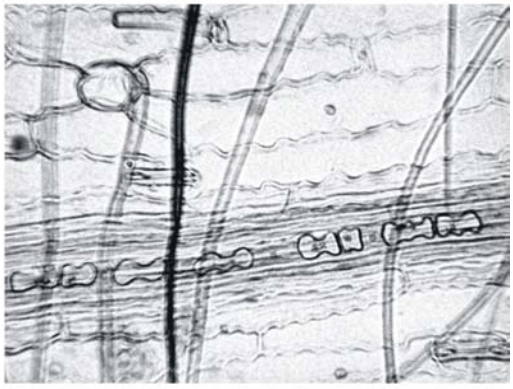
Pentaschistis aurea Acocks 24150
(7956) Marshy areas, fynbos.



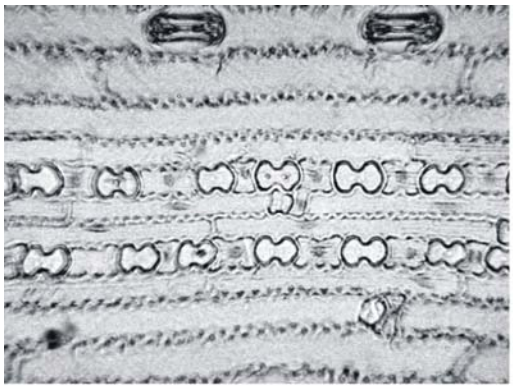
Pentaschistis barbata Ellis 5580
(7957) Coastal sands, fynbos.



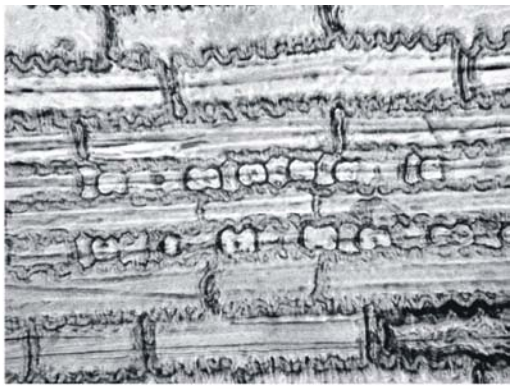
Pentaschistis basutorum Ellis 3292
(7960) Drakensberg slopes.



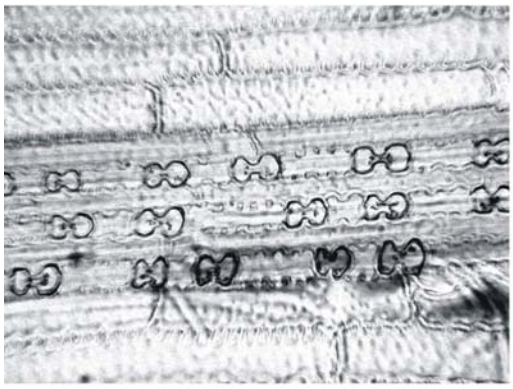
Pentaschistis capillaris Spies 4312 (7967)
Coastal sands, fynbos, west coast.



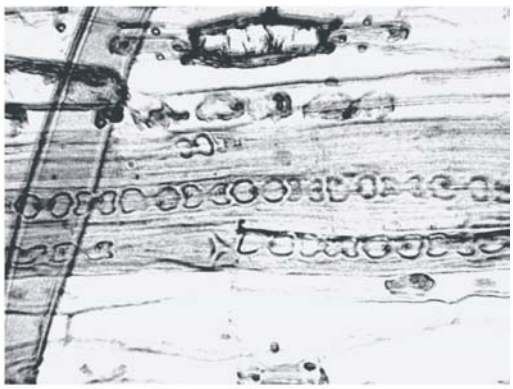
Pentaschistis cederbergensis Ellis 5586 (7968).



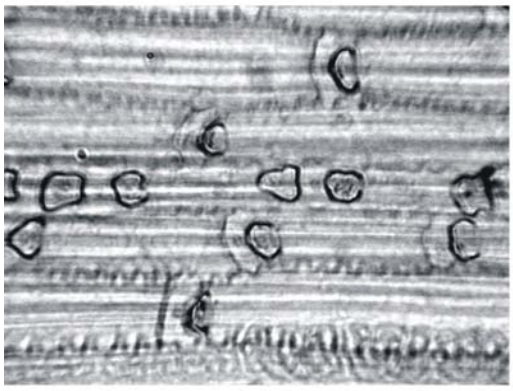
Pentaschistis chippendalliae Ellis 5734 (7971) Sour grassland, afromontane.



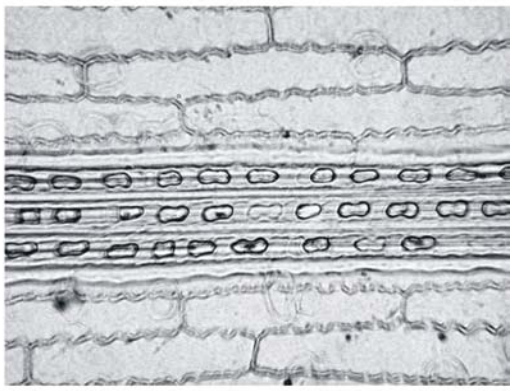
Pentaschistis colorata Ellis 5536 (7976) Stony slopes, sanstone derived soils, fynbos.



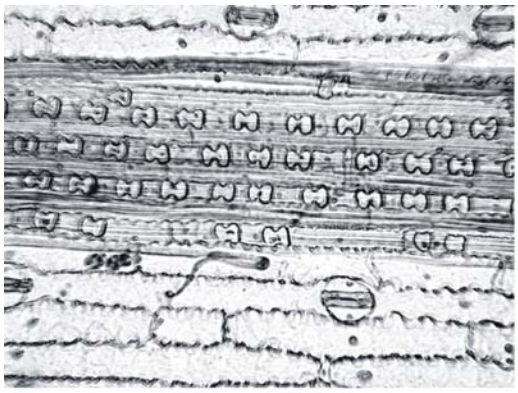
Pentaschistis densifolia Ellis 5584 (7980) Rock crevices, mountain slopes.



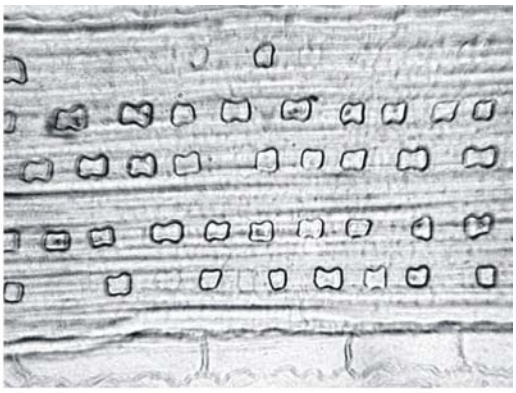
Pentaschistis elegans Ellis 2278 (7983) Coastal sands, fynbos.



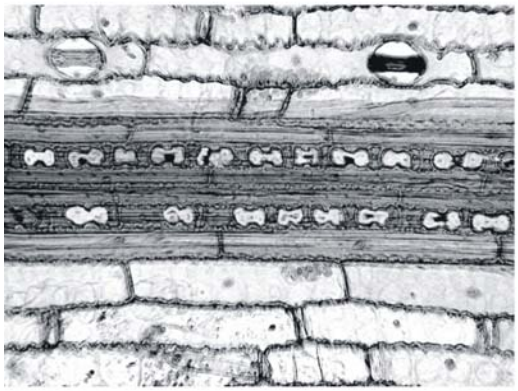
Pentaschistis galpinii Ellis 2398 (7987) Alpine grassland.



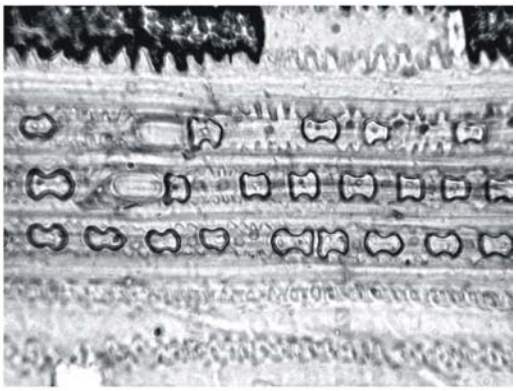
Pentaschistis glandulosa Ellis 5579 (7990)
Granite-derived soils, fynbos.



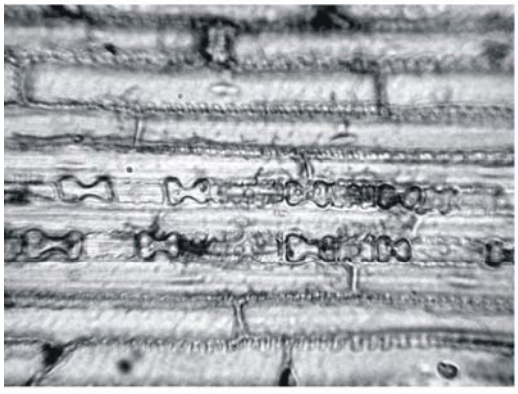
Pentaschistis microphylla Ellis 2592 (8004)
Arid montane grassland, Stormberg.



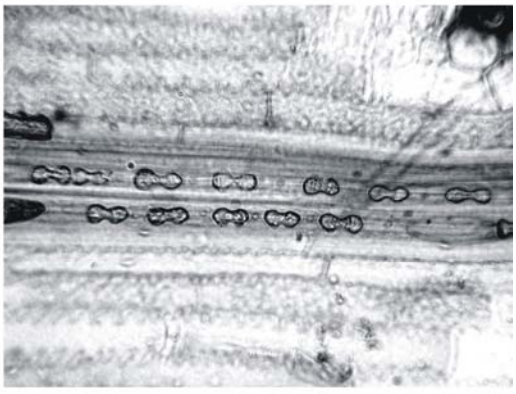
Pentaschistis natalensis Ellis 5735 (7992) Sour grassland, forest margins in afromontane belt.



Pentaschistis oreodoxa Ellis 2291 (7994)
Sour grassland, afromontane.

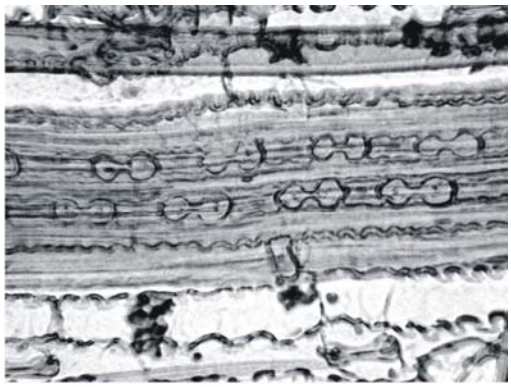


Pentaschistis pallescens Ellis 2226 (8006)
Lower slopes, sandstone mountains, fynbos.

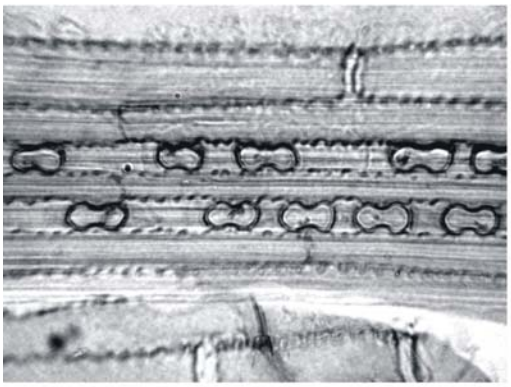


Pentaschistis patula Ellis 2306 (8008)
Sandy soils, arid margins, fynbos.

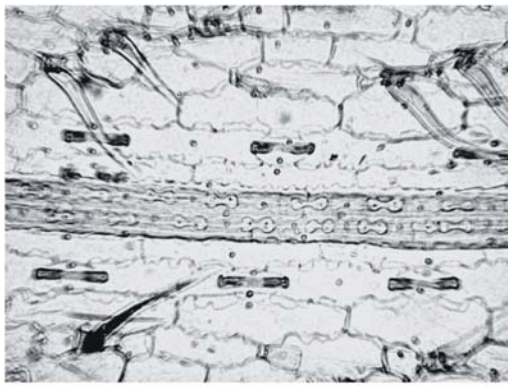
Pentaschistis pseudopallescens Ellis 5523 (8010) Seeps, streams, in sand, Cape fold mountains.



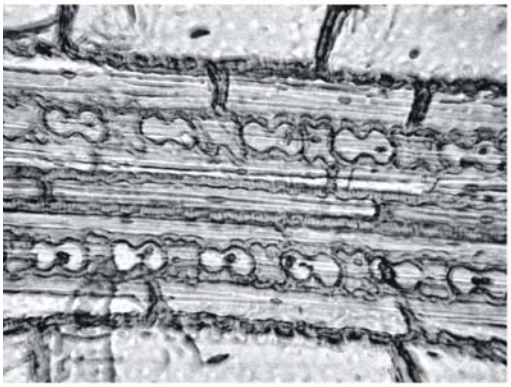
Pentaschistis rupestris Ellis 5596 (8014) Sandstone derived soils, fynbos.



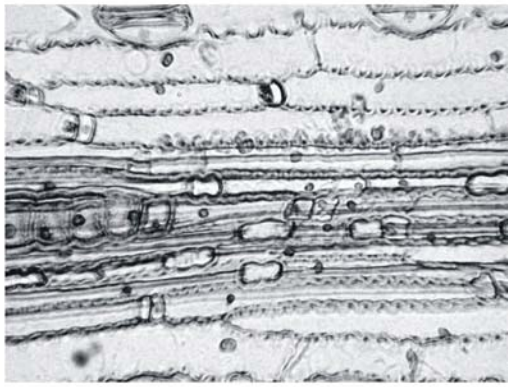
Pentaschistis setifolia Ellis 985 (8016) Sour grasslands, afromontane.



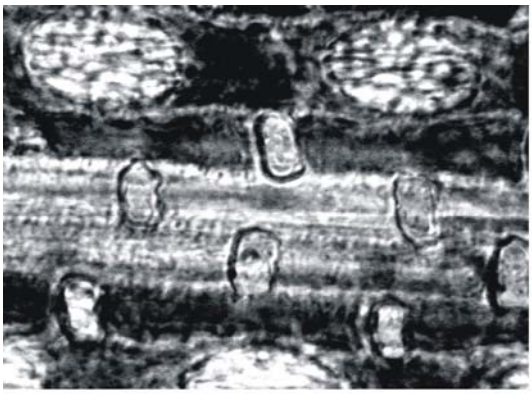
Pentaschistis tomentella Ellis 5420 (8018) Arid regions of Namaqualand.



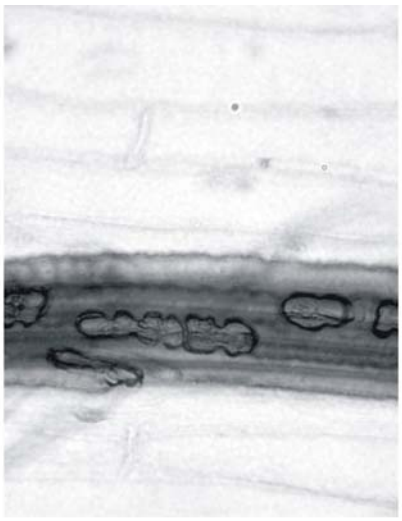
Pentaschistis tortuosa Ellis 5603 (8020) Damp places, sandstone derived soils, fynbos.



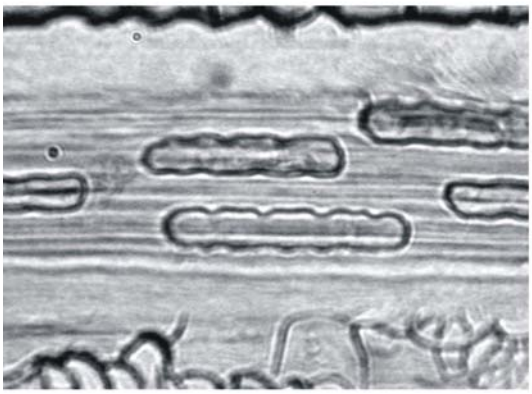
Pentaschistis triseta Ellis 5421 (8023) Sandy soils below 600m, fynbos.



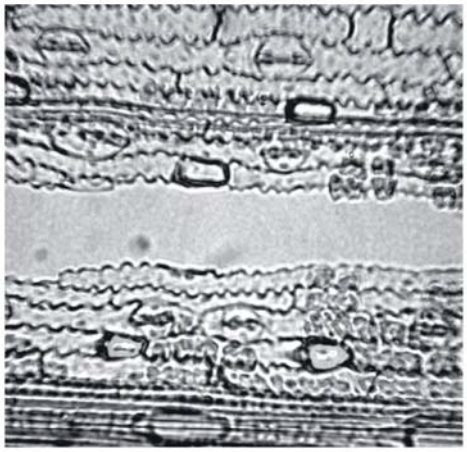
Phacelaris franksae Ellis 3283 (8499) Mountain grassland.



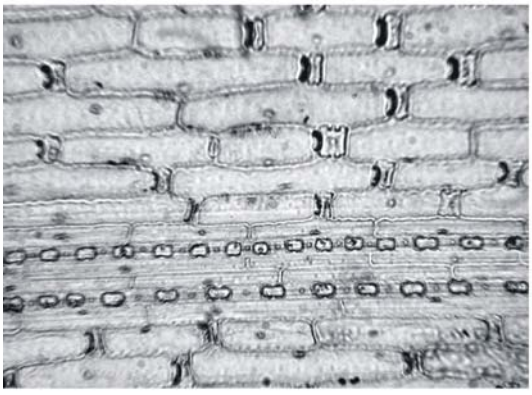
Poa binata Ellis 2852 (7851) Mountain slopes, moist areas.



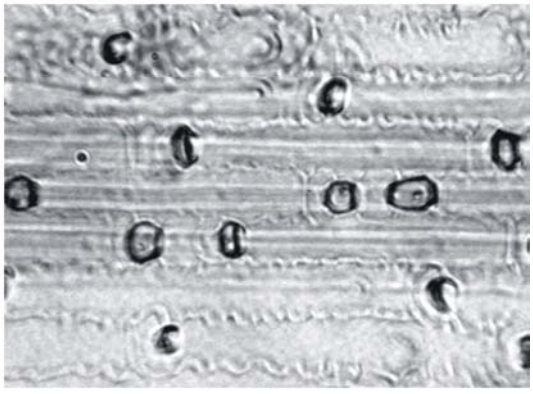
Poa bulbosa Ellis 2471 (7850) Seasonal pans, streamsides.



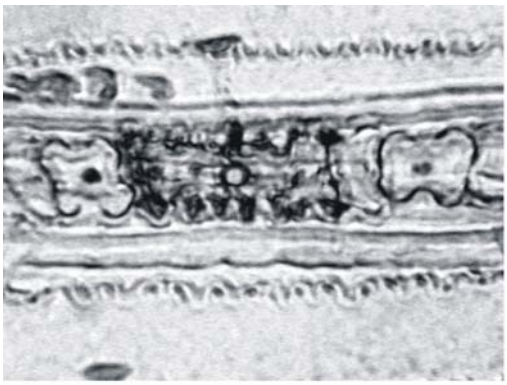
Prosphytochloa prehensilis Ellis 3783 (8148) Moist forests.



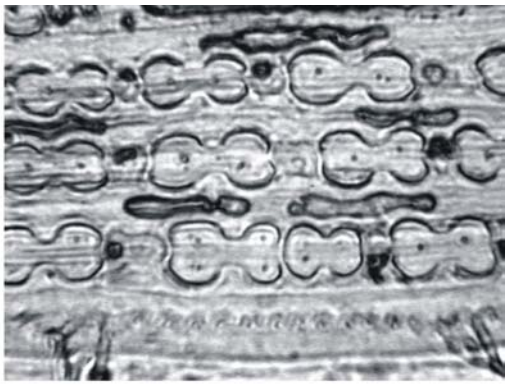
Pseudopentameris macrantha Ellis 2327 (8074) Mountain slopes, fynbos.



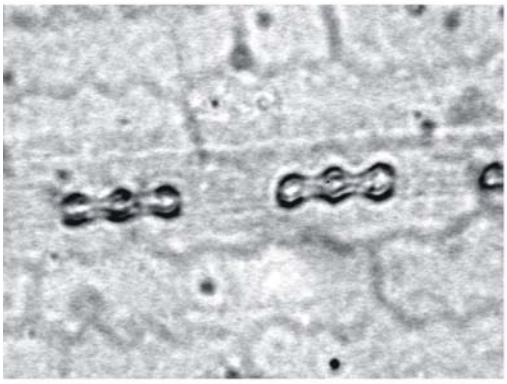
Puccinellia acroxantha Ellis 1674 (7860) Periodically flooded depressions.



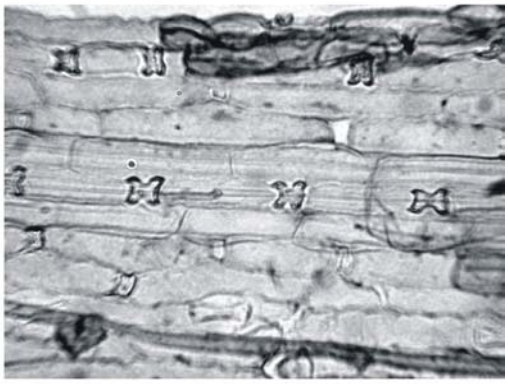
Rhytachne latifolia Ellis 4536 (8501)
Shades streamsides, woodland pans.



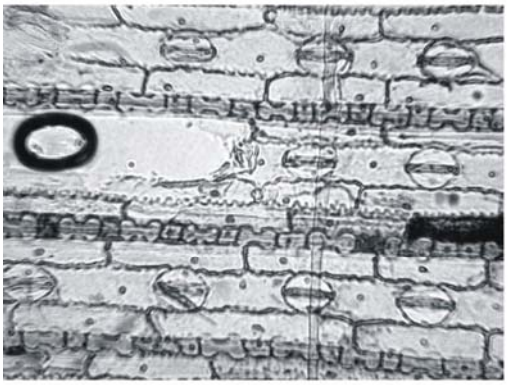
Rottboelia cochinchiniensis Ellis
3852 (8507) Wet places.



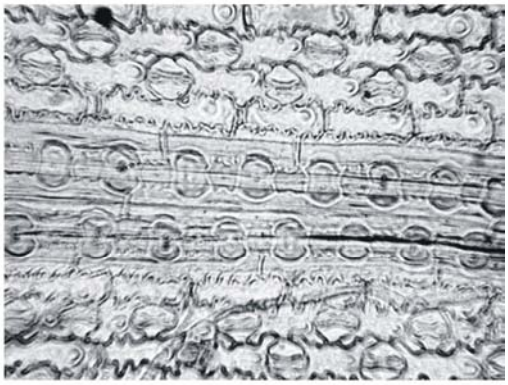
Sacciolepis curvata Ellis 3232 (8420) Damp,
shady places, forest undergrowth.



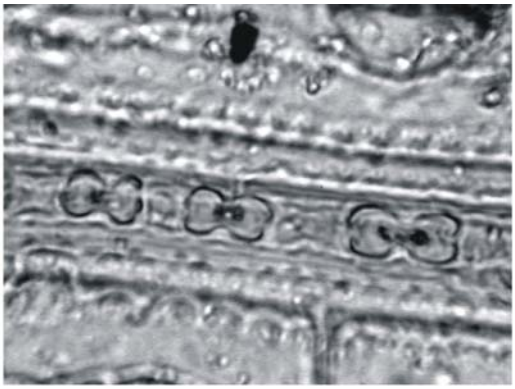
Sacciolepis typhura var. glaucescens Ellis
92 (8426), Swamps, marshy places.



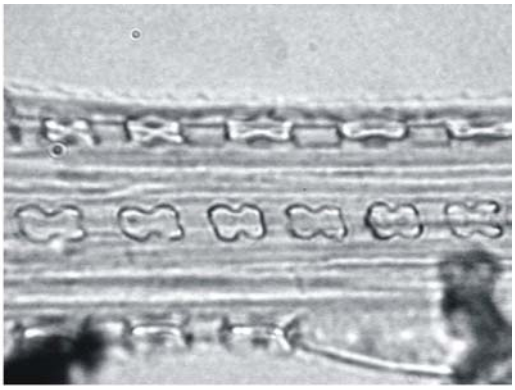
Schizachyrum sanguineum Ellis
4500 (8428) Open veld.



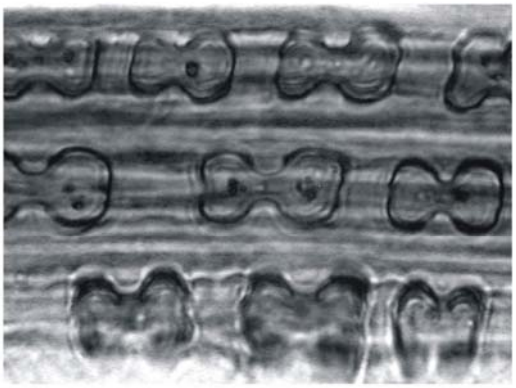
Schoenefeldia transiens Ellis 3867 (8133)
Open veld, seasonally flodded flats.



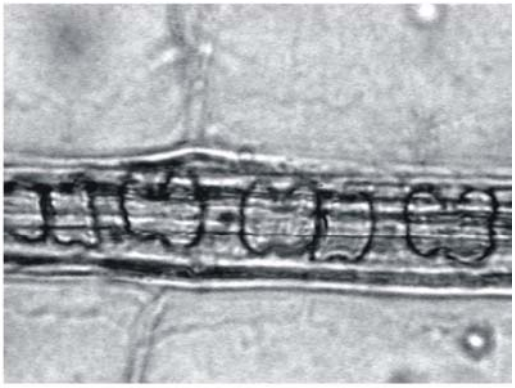
Setaria appendiculata Ellis 905 (8431) Rocky outcrops, among bushes, dry riverbeds



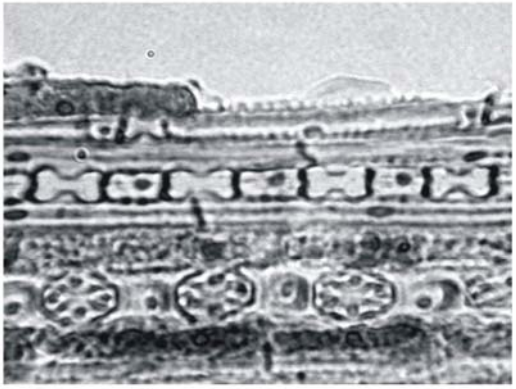
Setaria lindenbergiania de Wet 1066 (8435) Open woodland, forests, rocky hillsides



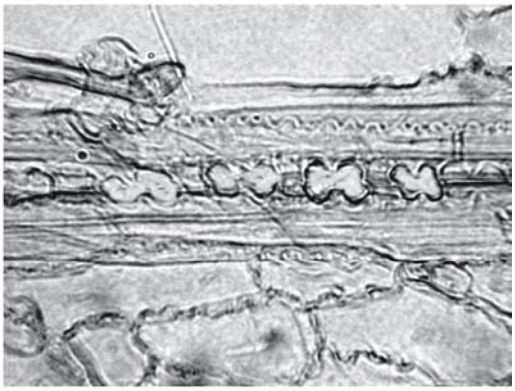
Setaria sphacelata Ellis 149 (8438) Moist places, hillsides



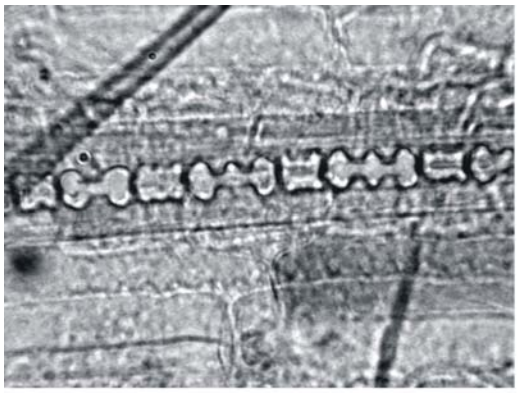
Setaria ustilata Ellis 2890 (8440) Dry bushveld regions, shade of trees, bushes



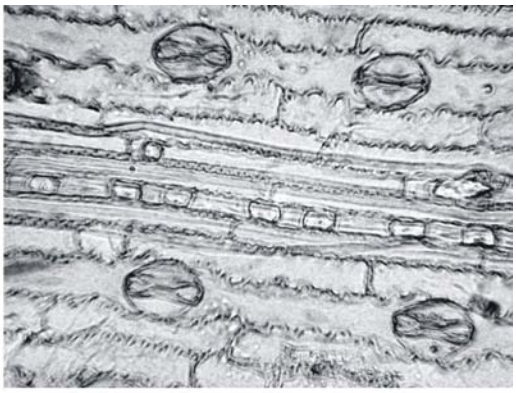
Sorghastrum friesii Ellis 3695 (8443) Wet places



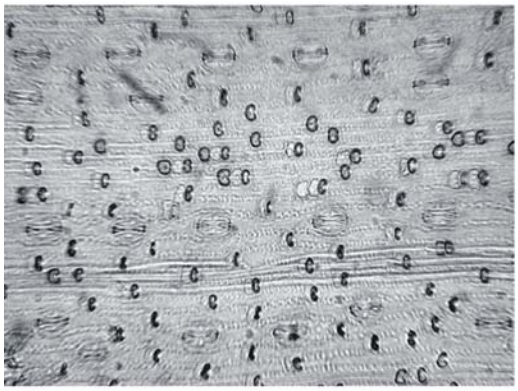
Sorghum bicolor Ellis 4429 (8445)



Sorghum versicolor Ellis 133 (8450)

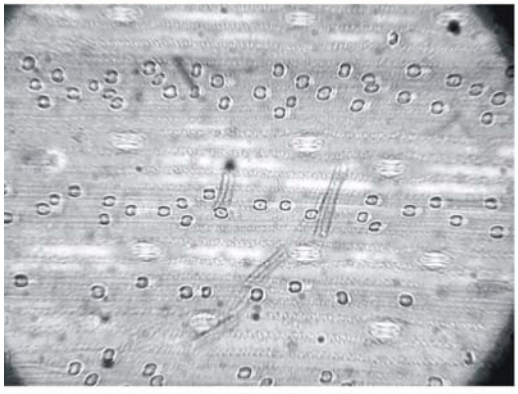


Sporobolus albicans Ellis 3658 (8134)
Limestone pans, dry depressions

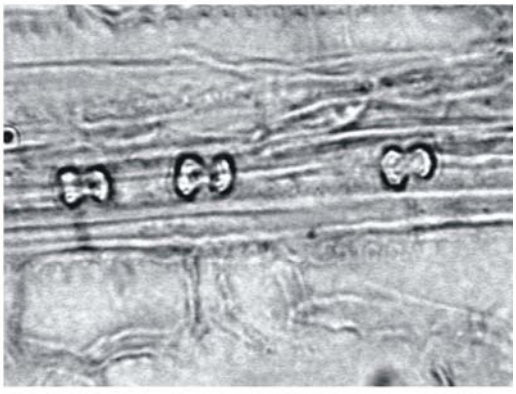


Sporobolus centrifugus Ellis 3658
(8135) High mountainveld

Sporobolus ludwiggi Ellis 850 (8136)
Damp calcareous soils, pans, vleis

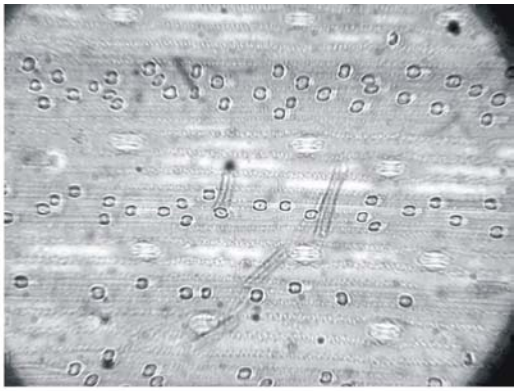


Sporobolus panicoides Ellis 1929 (8138)
Sandy, stony soils, hillsides

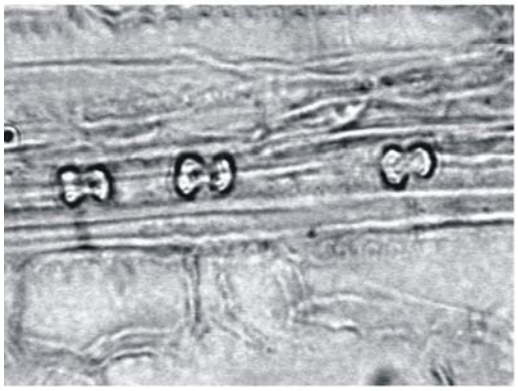


Stenotaphrum secundatum Ellis 267
(8454) Coastal beaches. marshes

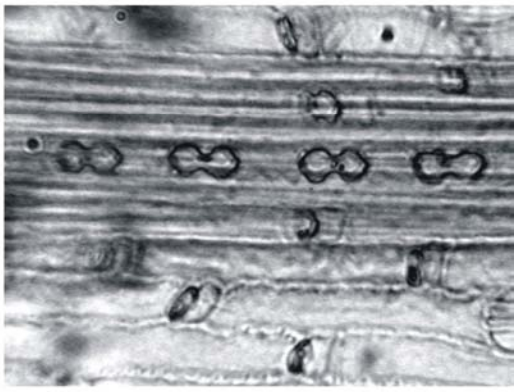
Stenotaphrum secundatum Ellis 267 (8454)
Coastal beaches. marshes



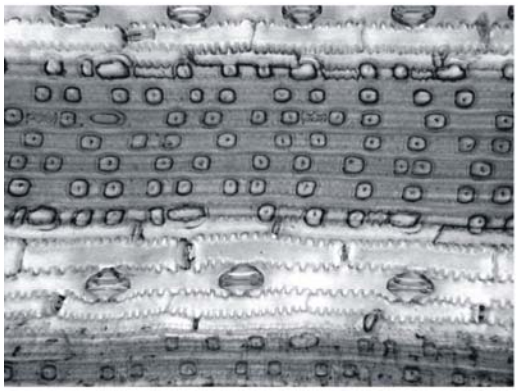
Stipa dregeana Ellis 2099 (8525) Forest



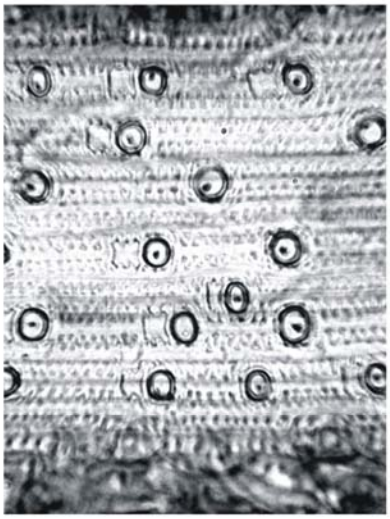
Stipagrostis anomala De Winter 3409 (7866)
Shallow sandy soils, open plains, arid regions



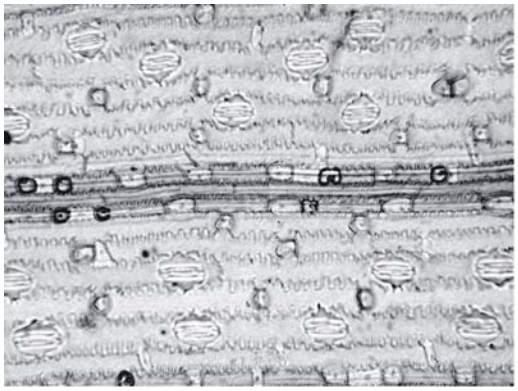
Stipagrostis brevifolia De Winter 3266
(7870) Open plians, arid regions



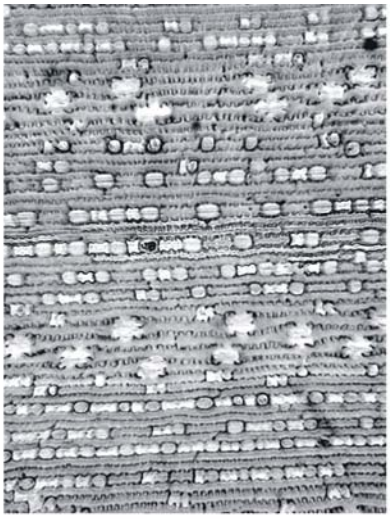
Stipagrostis damarensis De Winter
17837 (7872) Riverbeds, drainage
lines, arid regions



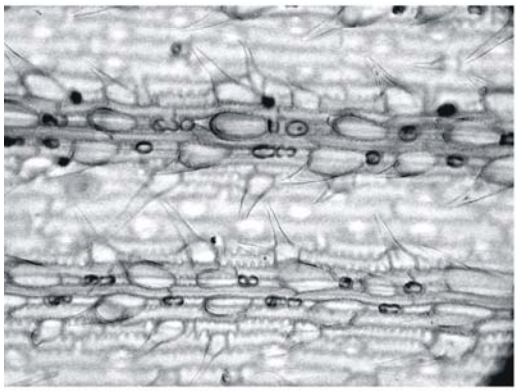
Stipagrostis dregeana De Winter
2572 (7874) Coarse sandy,
shallow soils, arid regions



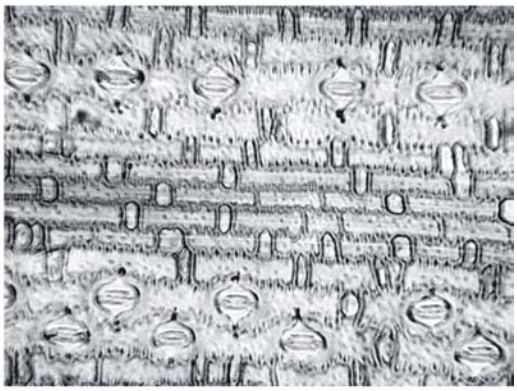
Stipagrostis fastigiata De Winter 3573 (7875) Sandy alkaline soils, arid regions



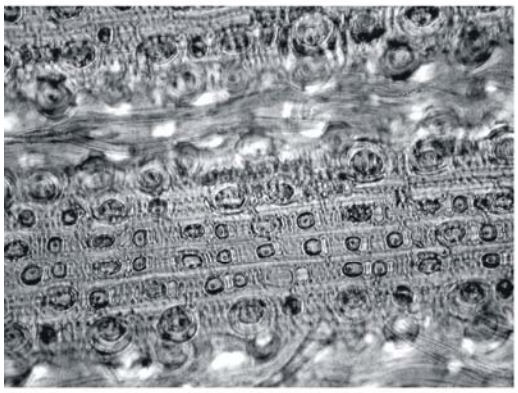
Stipagrostis garubensis De Winter 2289 (7877) Hillslopes, riverbeds, arid regions



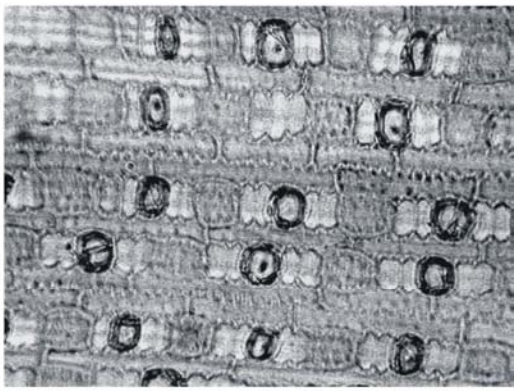
Stipagrostis hermanii De Winter Kinges 2634 (7881) Hills, open plains, arid regions



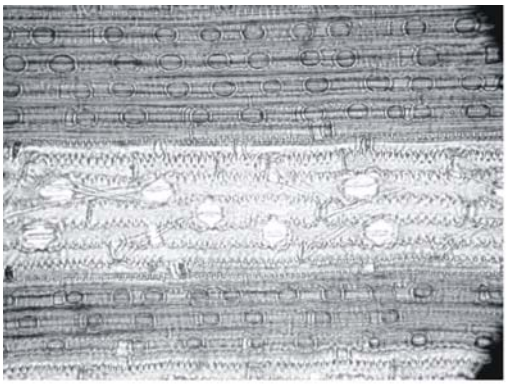
Stipagrostis lutescens De Winter Kinges 2445 (7888) Sandy soils, arid regions



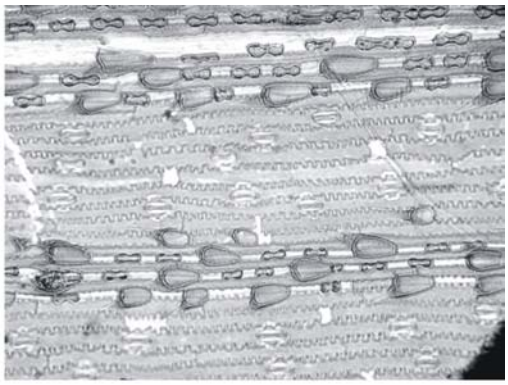
Stipagrostis proxima Flanagan 1657 (7891) Sandy soils, arid regions



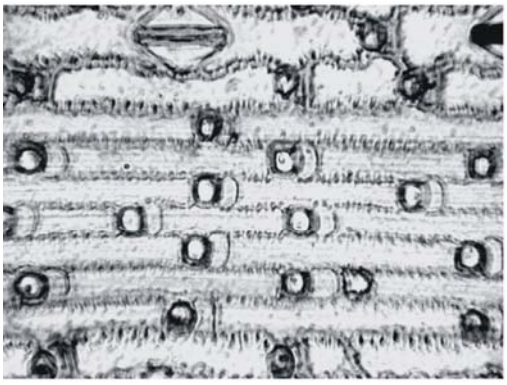
Stipagrostis sabulicola Keet 1612 (7894) Dunetops, sandy gullies, riverbeds, arid regions



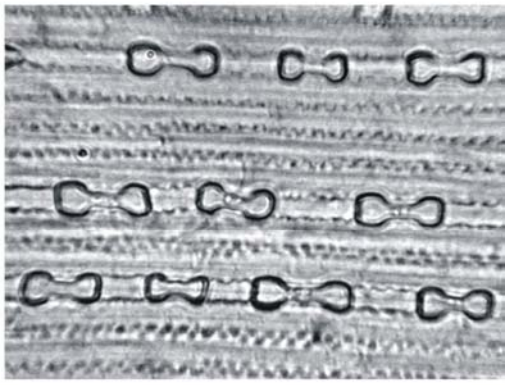
Stipagrostis schaeferii Kinges & De Winter 2586 (7896) Gravel plains, dry watercourses, arid regions



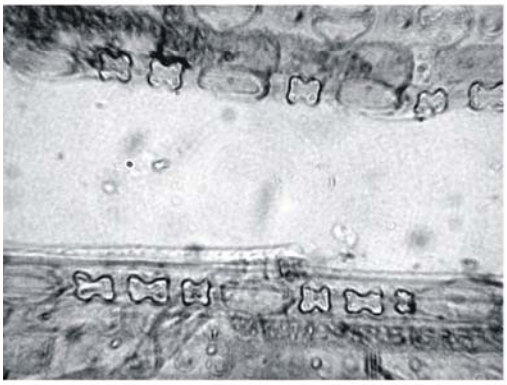
Stipagrostis subacaulis Schweick De Winter 2241 (7897) Coarse sandy soils, hillsides, arid regions



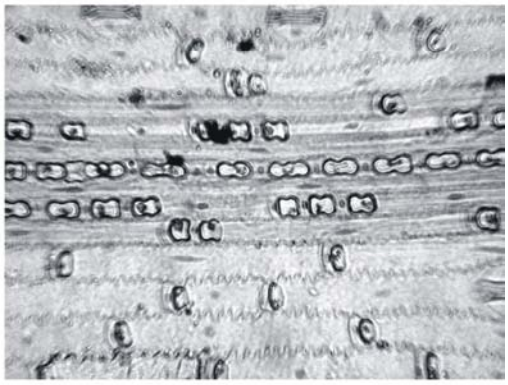
Stipagrostis zeyheri Bolus 12910 (7906) Sandy slopes, limestone hills, fynbos



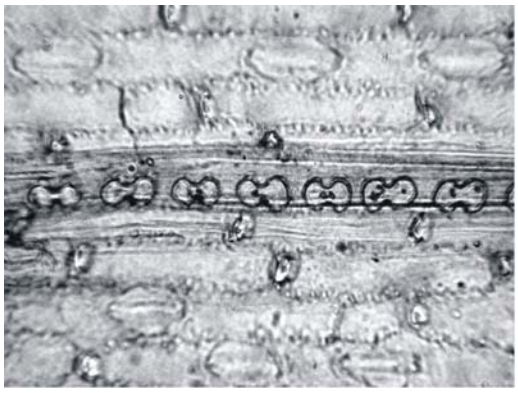
Styppeiochloa gynoglossa Ellis 3293 (8522) Rock crevices, seeps, rainfall above 800mm, high alt.



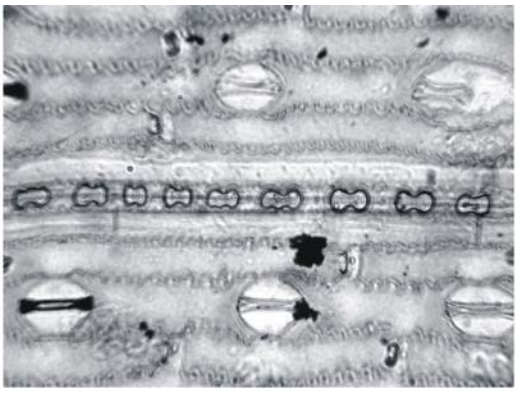
Themeda triandra Ellis 1670 (8458) Open veld



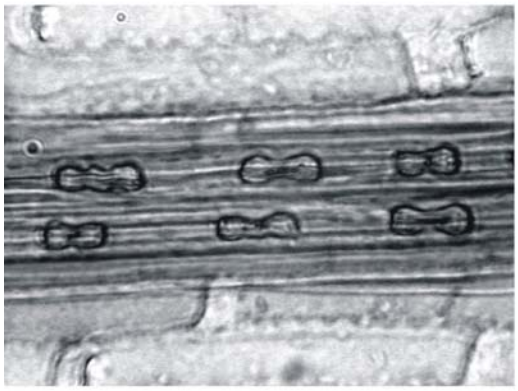
Tribolium acutiflorum Ellis 685 (8076) Sandy soils, fynbos



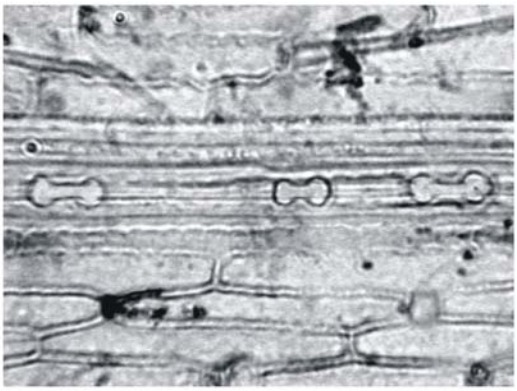
Tribolium alternans (Ellis 1210 (8082)
River flats, sandy soil, fynbos



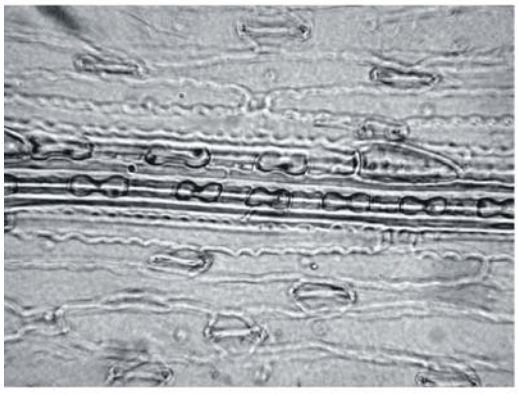
Tribolium brachystachyum Ellis 2213
(8080) Mountainous terrain, fynbos



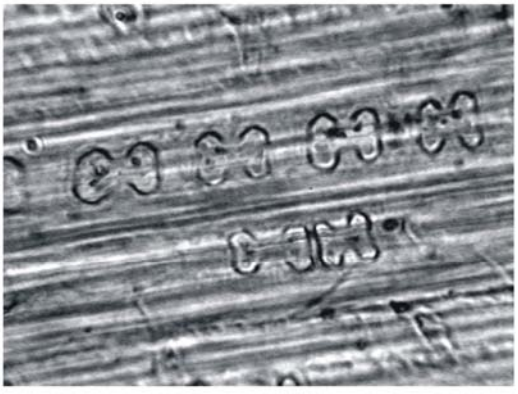
Tricholaena monachne Ellis 1935
(8463) Sandy soil, open veld



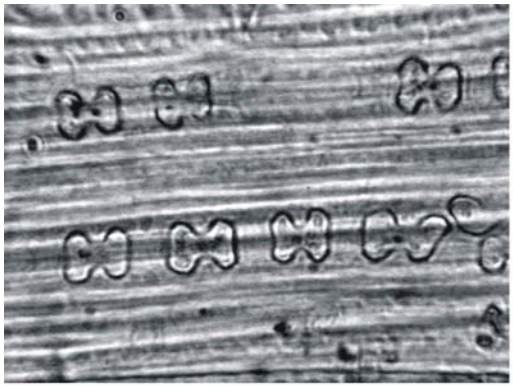
Trichopteryx dregeana Ellis 454 (8460)
Vleis, wet places, shady crevices



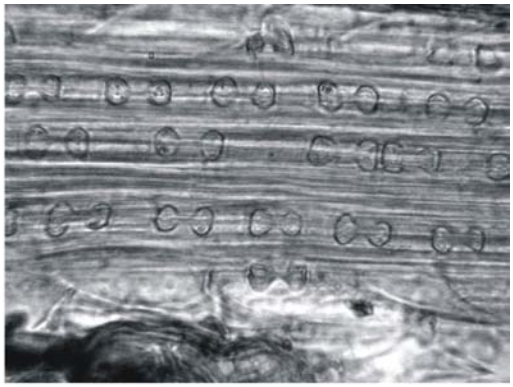
Triraphis purpurea Ellis 4367 (8141) Moist
places, shade, calcareous soils



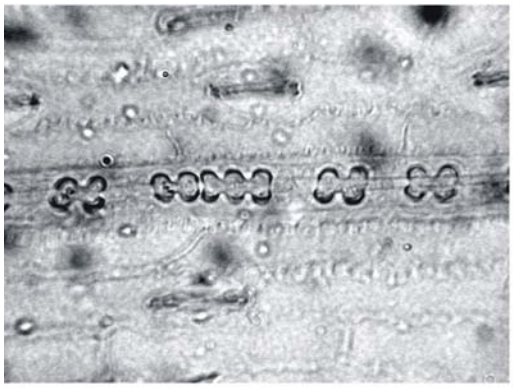
Tristachya biseriata Ellis 1333
(8467) Hillsides, rocky outcrops



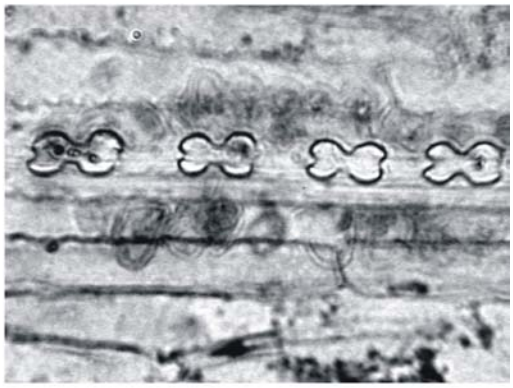
Tristachya leucothrix Ellis 297 (8468)
Marshy grassland, mountain sourveld



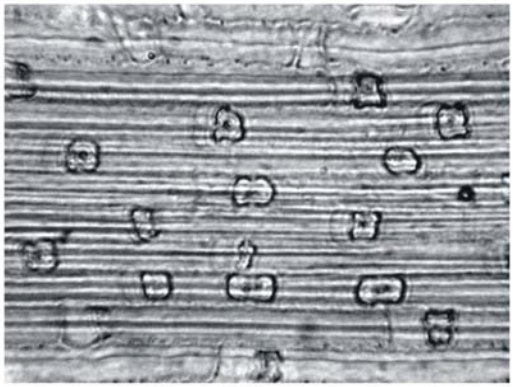
Tristachya rehmannii Ellis 1382
(8471) Open veld



Urochloa brachyura Ellis 407
(8475) Woodland, shade



Urochloa mosambicensis Ellis 503
(8478) Sheltered places



Vetiveria nigritana Ellis 579 (8481)
Wet places

Appendix 3: Indicator matrix of GSSC-morphotypes recorded in 309 grass species.

BINARY INDICATOR MATRIX
(Table 3: Association through Rate of Recurrence)

Appendix 4: Spearman's rank-order correlation between association through rate of recurrence of morphotypes and relative abundance of morphotypes.

Appendix 4.

Spearman's rank-order correlation between association through rate of recurrence of morphotypes and relative abundance of morphotypes. Bivariate plots with 95% confidence limits show positive covariation between the two categories.

Variable	Spearman Rank Order Correlations MD pairwise deleted. Matrix of two lists (Frequency vs Relative Abundance) Marked correlations are significant at p <.05000

Appendix 16: Comparison of GSSC-phytoliths against three Palaeoenvironmental Scenarios.

Introduction

GSSC-phytolith morphotypes demonstrated their likely ability to predict a range of ecological and climatic conditions within the South African environment. The potential strength of the method was evaluated against several palaeoenvironmental interpretations provided by three fossil faunal assemblages located in the Grassland Biome (Figure 1). The faunal assemblages reflect palaeoenvironmental conditions at important stages of mammalian evolution in the central interior of southern Africa (Figure 2). The aim of this exercise was to compare these palaeoenvironmental interpretations with the results of analyses done on fossil phytolith samples, by using the Habitat- and Rainfall-categories as frameworks for interpretation.

Two assemblages are derived from Cornelia-Uitzoek and Florisbad, which are respectively the type localities of the Cornelian and Florisian Land Mammal Ages Age (*vide* Hendey 1974; Brink 1987, 1988; Brink and Rossouw 2000). A Land Mammal Age (LMA) is a period of geological time defined by its distinguishing faunal character (Hendey 1974).

The site of Cornelia-Uitzoek consists of fossil-bearing clays and fluvial gravels that are exposed along erosional gullies next to the Schoonspruit River on the Uitzoek farm near the town of Cornelia (Figure 3; Butzer 1974; Bender and Brink 1992) The vertebrate fauna from Cornelia-Uitzoek is an important representative sample of the southern African Middle Pleistocene (Cooke 1974; Bender and Brink 1992) and

considered to be coeval with the upper Beds of Olduvai, which suggests an age of between 800 000 and 1 million years ago for the site (Brink and Rossouw 2000). Latest excavations at the site suggest that carnivores may have been the primary collecting agent of the fossil accumulation (Brink and Rossouw 2000). The occurrence is rich in medium-sized ungulates with the extinct bovids, *Antidorcas bondi*, *Damaliscus niro* and *Connochaetes gnou laticornutus* representing the dominant taxonomic component (Brink and Rossouw 2000). These species, along with other extinct ungulates including the bovids, *Megalotragus eucornutus*, *Pelorovis antiquus*, and three equid species are regarded as indicator taxa for the incipient development of an open grassland ecosystem in the central interior of southern Africa (Brink and Rossouw 2000).

Florisbad, situated forty-five kilometers northwest of Bloemfontein, is the type locality of the Florisian Land Mammal Age (Hendey 1974) and consists of a fossil-bearing and archaeologically rich spring mound that has produced two distinct faunal assemblages, a Middle Stone Age land surface assemblage with evidence of human habitation and an older spring assemblage (Brink 1987, 1988). The Florisbad spring assemblage is between 100 000 and 400 000 years old and has produced hominid remains that yielded an ESR–date of 259 000 ± 35 000 yrs BP (Grün *et al*. 1996). Fossils from this occurrence are primarily derived from a carnivore- accumulated assemblage, excavated from intrusive spring vent structures that continually reworked and included fresh faunal material from around the spring and associated waterholes (Figure 4). Despite the temporal range of ESR age estimates, the spring assemblage is regarded as a homogeneous taphonomic entity (Brink 1988).

Classification of taxa according to habitat types, reflect a local spring environment indicated by the occurrence of hippopotamus and lechwe, as well as an open regional environment, indicated by a number of extinct grazers, including *Equus capensis, Pelorovis antiquus, Damaliscus niro, Megalotragus priscus* and *Antidorcas bondi,* The faunal composition reflect productive grassland conditions and a grazing system that is analogous to the grazing succession described for the modern sub-Saharan savannas in East Africa (Bell 1971; Brink 1987, 1988; Brink and Lee Thorp 1992). In addition, a study on the feeding niche of the extinct springbok *A. bondi* also established the existence of C_4 grasslands in the region (Brink & Lee Thorp 1992). The third faunal assemblage is derived from a recent discovery of fossiliferous fluvial sediments at Erfkroon, sixty kilometers southwest of Florisbad, which in part represent the terminal period of the Florisian LMA in the central interior of southern Africa (Figure 5). The site covers several hectares of river channel and overbank silts and clays flanking the modern Modder River (Churchill *et al.* 2000). New excavations are currently in progress and preliminary luminescence dating indicates that the overbank sediments span the last 160 000 years with several distinctive pedostratigraphic units dating to just before the start of the Last Glacial Maximum (Figure 3C; Churchill *et al.* 2000; J.S. Brink pers. com.). The site preserves vertebrate fossils that are typically Florisian in character, as well as birds, amphibians, small reptiles, fish and micromammals, which is also representative of a more complex riverine environment (Churchill *et al.* 2000; J.S. Brink pers. com.). Geologically, the exposed sediments reflect the evolution of the Modder River system during the Late Pleistocene, and it has been suggested that the extensive channel sedimentation and

overbank deposits developed under changing palaeoclimates that ranged from semiarid to arid (Churchill *et al.* 2000).

Materials and Methods

Materials

Four sediment samples, were collected from the temporally homogenous, fossil bearing yellow clay unit at the Cornelia-Uitzoek type site (Figure 3). Each sample was removed from the fossil-bearing unit in the form of consolidate blocks. Three hyaena coprolites were sampled from the Florisbad spring assemblage collection stored at the Florisbad Quaternary Research Station. Two of those (FLO1050 and FLO1051) were previously sampled for the extraction of pollen (Scott and Brink 1992) while the third had been analysed for phytoliths as part of a preliminary study (Scott and Rossouw 2005). The coprolites were analysed with consideration that the context of the spring assemblage was disturbed as a result of vertical displacement and post-depositional modification of bone by ancient intrusive spring vent structures (Figure 2B; Brink 1988). Although direct proof is difficult to establish at present, the possibility exist that the fossil coprolites may be temporally and taphonomically linked to the dated hominid remains due to their direct association with hyaena activity at the spring. Six sediment samples were collected from a pedostratigraphic sequence dated to between 25 600 ± 1200 years and 42 000 ± 2000 years BP by luminescence dating (Figure 5; J.S. Brink pers. com.). The samples were extracted with a small corer after initial cleaning of the section facies.

Phytolith extraction and assemblage analysis

The procedure for recovering phytoliths from coprolite and soil samples is based on published techniques (Piperno, 1988; Lentfer and Boyd, 1998, 1999; Albert and

Weiner, 2001; Horrocks, 2005). Only half of each fossil coprolite sample was used for the extraction of phytoliths. To avoid potential contamination, the outer layer of each sample was removed by submerging the coprolites in a solution of HCl (10%) for five minutes where after it was rinsed at treated the same as the sediment samples. The sediment samples were collected in consolidated blocks to minimize potential contamination. Ten different modern soil samples were collected in the vicinity of each fossil locality. Each set was then mixed up and analysed as one representative sample per site. Twenty grams of soil for each sample was used for each phytolith extraction. Essential steps included deflocculation, removal of clays by means of sedimentation and the elimination of carbonates using HCl in low concentration (10%). Phytolith extraction involved mineral separation with a heavy liquid solution of sodium polytungstate (specific gravity = 2.3). Fractions were mounted on microscope slides in glycerin jelly or DPX mountant. The phytolith counts are based on systematic scanning following standardized transects for each slide and identification at X400 magnification (Table 1).

Phytolith counts were normalized as percentages of the short-cell sum for each sample (Figure 6), based on the total count of the eleven GSSC-morphotypes (acknowledged in Chapter 2, Table 2), and incorporated into the modern dataset of GSSC-profiles that were created for the Habitat- and Rainfall-category in Chapter 2, Table 6 (Table 2). The combined dataset was analyzed using CA by applying the GSSC-morphotypes that were found to be significant for the Habitat- and Rainfall-categories (see Chapter 5, Table 22). The CA for the Rainfall-category was carried out in order to substantiate the trends observed in the CA conducted for the Habitat-

category.

Results

The first CA carried out for the Habitat-category resulted in two dimensions explaining a cumulative 90.2% of inertia, with a total of three dimensions extracted (Table3, Figure 7). While there is some overlap amongst habitat-subcategories, the CA did show that the inertia created by the matrix apparently distributed the fossil samples across the plot according to a climatic gradient. The first dimension accounted for 65.7% of the inertia and was clearly driven by growing temperature, with predominantly C_4, warm growing-temperature environments represented by the Savanna grassland-subcategory (highest contribution to total relative inertia = 0.051476), and predominantly C_3, cool growing-temperature environments marked by the High altitude grassland- category on the other end of the graph (highest contribution to total relative inertia = 0.214589). Dimension 2, accounting for 26% of the inertia, indicated a moisture gradient, with wetter habitats marked by the High altitude grassland- category and drier habitats marked by the Succulent Karoo-subcategory at the bottom of the graph (Figure 7).

The second CA conducted for the Rainfall-category confirmed the trends observed in the first CA. It resulted in two dimensions explaining a cumulative 77.8% with a total of five dimensions extracted. Dimension 1 accounted for 53.4% of the inertia and clearly showed a seasonal grade marked by the >500mm Summer Rainfall- and >40% Winter Rainfall-subcategory, while the second dimension accounted for 24.4% of the inertia and reflected a wetness gradient (Table 4, Figure 8).

The Cornelia specimens indicated their affiliation with the Savanna grassland- and Nama-Karoo grasses – subcategories in the first CA and the <500mm Summer Rainfall-subcategory in the second CA. The Florisbad spring assemblage material demonstrated more diverse trends. COR59 did not plot closely to any subcategory, but was more inclined towards the Fynbos grasses-, and Swamps/Vleis-subcategories in the first CA and the >40% Winter Rainfall subcategory in the second CA. FLO1050 and FLO1051 fell closer to the Nama-Karoo grasses and >500mm Summer Rainfall subcategories. Alliances amongst the Erfkroon samples were mainly with the Desert grasses-subcategory in the first CA, except for ERF5 and ERF7a, which respectively associated closer to the Fynbos grasses- and Nama-Karoo grasses-subcategories. The second CA indicated that the Erfkroon samples associated closely with the >40 Winter Rainfall-subcategory.

Discussion and Conclusion

The fossil phytolith data from Cornelia-Uitzoek suggests that relatively warm and dry C_4 grassland conditions, analogous to Savanna grassland or Nama-Karoo environments, prevailed during the time of bone accumulation at the site. The plots indicated a wooded grassland component, represented by the Savanna grassland-subcategory, but also warmer and drier than present summer rainfall environments, as represented by the Nama-Karoo grasses subcategory. The Nama-Karoo Biome today is a complex of extensive plains dominated by low shrubs intermixed with grasses where small trees occur only along drainage lines or rocky outcrops (Mucina *et al*. 2006b) Nama-Karoo-type conditions could be indicative of incipient treeless grassland development. However, the data also implies that open grasslands were

probably not as established as previously inferred from the faunal record (Brink and Rossouw 2000).

Phytolith data from Florisbad samples, FLO1050 and FLO1051 affiliated closely with the Nama-Karoo grasses-subcategory in the first CA and more generally with the >500mm Summer Rainfall-subcategory in the second CA. The Nama-Karoo Biome forms a dry ecotone between the winter-rainfall Fynbos Biome in the south and the summer rainfall Savanna Biome in the north, with summer rainfall occurring mostly in late summer (Mucina *et al.* 2006c). This trend concurs partly with pollen results of FLO1050 and FLO1051 from the Scott and Brink (1992) study, which showed dry pan floor elements like Chenopodiaceae pollen, and relatively high proportions of Asteraceae pollen, which is a dominant plant family in the Nama-Karoo Biome. The Asteraceae pollen was associated with low rainfall, but with a seasonality-shift away from summer rains (Scott & Nyakale 2002; Scott & Lee-Thorp 2004; Scott and Rossouw 2005). However, the absence and comparatively low amount of *Stoebe*-type pollen in FLO1050 and FLO1051 respectively, is probably related to a mesic C_4, summer rainfall environment (Scott and Rossouw 2005), which is also indicated by the plots in the second CA. The position of FLO59 in the two-dimensional matrix of the first CA was more representative of swampy conditions at the local spring environment than of the wider regional grassland, while its position in the second CA also corresponded to a mesic C_4, summer rainfall environment. An indication of swampy conditions was pointed out by the comparatively high proportions of Trapeziform morphotypes in the sample (Figure 6), which appear to be generally good indicators of swampy conditions and permanently damp soils (Table 22).

The phytolith data from the spring assemblage coprolites demonstrated the presence of a C_4 grassland ecosystem with a local aquatic component at Florisbad, which is in accordance with the faunal evidence (Brink 1988; Brink and Lee Thorp 1992). However, there were no association between the phytolith data and the modern Grassland Biome-subcategory. Although the results are in line with the pollen data from FLO1050 and 1051, reconciling summer rainfall and Nama-Karoo-type conditions with a productive grassland ecosystem in the spring assemblage most likely suggest that a unique grassland ecosystem with no modern analogue existed at the time.

Phytolith data from Erfkroon indicated cool and dry Desert- to Fynbos-like conditions between 42 000 years and 26 000 years ago. The results are supported by pollen evidence from the Tswaing Crater sequence in the current Savanna Biome about five hundred kilometers north of Erfkroon, that indicate aridification of grasslands between 33 000 and 40 000 thousand years ago, and cool dry grassland with fynbos elements at around 33 000 years ago (Scott 1999), while grass phytoliths from the same sequence suggest that C_3 grasses increased in the region between 29 000 and 8000 years ago (McLean and Scott 1999). The evidence support the hypothesis that the fluvial overbank deposits at Erfkroon developed under conditions that ranged from semiarid to arid (Churchill *et al.* 2000).
